National Council for Technological Awards

THE report of the National Council for Technological Awards for the period April 1960 to March 1961 (London: National Council for Technical Awards. Pp. 37) records that nearly 5,000 students were following courses leading to the diploma in technology, compared with 3,800 a year ago, and 309 diplomas were awarded, bringing the total to 472. Approximately 83 per cent of the engineering students and 56 per cent of students of other technologies are working in industry, and the Council is impressed by the increase in the number of students following sandwich courses in technologies other than engineering, from 219 in November 1957 to 1,246 at the end of the year under review; for engineering sandwich courses the corresponding figures are 652 and 3,191. Of 1,769 students enrolled in first-year courses leading to the diploma in the current session, 63 were women. Almost 25 per cent of these students entered their courses by virtue of holding good Ordinary National Certificates, and the Council points out that but for the development of these courses few of these students would have had an opportunity of gaining a qualification equivalent in standard to a university honours degree, and many might never have been added to the nation's technological man-power. The diploma is now accepted as a qualification for entry to the Scientific Civil Service equivalent to a university degree, and most professional institutions exempt holders of the diploma from taking the whole of their own examinations for graduate membership. The Council expresses appreciation of two awards from the Nuffield Foundation in support of study of the nature of courses leading to the diploma: one at the Brunel College of Technology concentrates on the relation of college periods of study to industrial training periods, and the other at the Birmingham College of Advanced Technology is concerned with the spacing of industrial and college training with the object of assembling a body of thought and opinion as a basis for deciding whether changes are needed to improve the quality of industrial and college training, increase the numbers attending advanced courses, and mobilize more effectively the teaching and research resources of colleges and companies. List No. 13 issued also by the Council details 100 existing and 13 proposed courses leading to the diploma.

The Calouste Gulbenkian Foundation, Lisbon

THE trustees of the Calouste Gulbenkian Foundation, Lisbon, have announced the grants made during the first half of 1961, which total about £360,000, and, of which, grants in the United Kingdom and British Commonwealth total nearly £100,000. Again they include grants for three years to British undergraduate scientific expeditions, as follows: £200 to the Royal Geographical Society in aid of the expeditions; £200 to the University of Leicester expedition to East Greenland; £200 to the University of Wales expedition to Mount Sabalan; £150 to the Cambridge Arctic Canada expedition; £100 to the University of Oxford expedition to the Andes of Peru; £100 to the University of Oxford expedition to the Atlas Mountains of Southern Morocco; £100 to the Cambridge expedition to Nagir, Karakoram; £100 to the Oxford expedition to the South Caspian; and £50 to the University of Oxford women's expedition to the Madeiras. The grants made in aid of education in Great Britain and the Commonwealth total £41,800, including: £15,000 to the School of Oriental and African Studies, University of London; £4,500 to the Science Masters' Association; £3,900 for three years to the School Library Association. In Portugal, £56,241 has been granted in aid of science and medicine, including grants for the Santa Maria Hospital, Lisbon, for biochemistry at the University of Oporto, the Laboratory of Mass Spectrometry of the Nuclear Energy Study Commission and the Centre of Geological Studies, Lisbon. A total of £7,500 has been given to the Faculty of Engineering of the University of Baghdad. Other countries receiving grants include Brazil (£8,508) and France (£2,612). Grants have also been made to the World Federation for Mental Health and the International Union against Cancer.

Fellowships for Plankton Research

IN order to encourage research relating to plankton in the western North Atlantic, the Lamont Geological Observatory is offering several fellowships for independent studies in this field. These fellowships are open to qualified scientists of any nationality, and include transportation costs from home to Sandy Hook, New Jersey, and return, plus a stipend which will be limited ordinarily to 1,500 dollars. Applications and requests for further information should be addressed to the Director, Sandy Hook Marine Laboratory, P.O. Box 428, Highlands, New Jersey.

Carlsberg-Wellcome Travelling Research Fellowships

THE Carlsberg Foundation (Copenhagen) and the Wellcome Trust (London) have announced the award of Carlsberg-Wellcome Fellowships for 1960–61 to: Dr. E. Poulsen, senior Lecturer at the Royal Veterinary and Agricultural College, Copenhagen, who will work at the Medical Research Council's Toxicology Research Unit at Carshalton on the neurotoxic influence of alicyclic phosphates and similar compounds; Dr. A. F. Hayward, of the Anatomy Department of the University of Glasgow, who will work at the Carlsberg Laboratory in Copenhagen, under the direction of Dr. H. Holter, studying the electron microscopic appearances in pinocytosis; Dr. S. L. Rowles, a member of the external scientific staff of the Medical Research Council at the School of Dental Surgery in Birmingham, who will work with Dr. Tovborg Jensen of the Royal Veterinary and Agricultural College, Copenhagen, on the chemistry of the calcium phosphates with special reference to those occurring in oral tissues.

Society for Applied Bacteriology

AT the annual meeting of the Society for Applied Bacteriology held in Wye on July 11 the following were elected officers of the Society: *Honorary President*, Mr. G. Sykes; *Honorary Secretary*, Dr. Ella M. Barnes; *Honorary Treasurer*, Mr. G. Elis Jones; *Honorary Editors*, Dr. S. E. Jacobs and Dr. D. J. Jayne-Williams; *Honorary Publications Manager*, Mr. A. H. Walters; *Honorary Advertising Manager*, Mr. E. J. Mann; *Members of Committee*, Mr. B. M. Gibbs, Dr. N. D. Harris, Dr. Agnes A. Nichols, Dr. J. R. Norris, Dr. A. M. Paton, Dr. Patricia M. Scholes, Dr. A. Seaman, Dr. Joan Taylor, Dr. G. C. Ware.

Australian Mammal Society

The following officers and council members were elected for 1961–62 at the third general meeting of the Australian Mammal Society, held in Brisbane, Australia, on May 26: *President*, Dr. G. B. Sharman; *Vice-President*, Dr. W. D. L. Ride; *Secretary*, Dr. R. G. Chittleborough; *Treasurer*, Mr. J. A. Thomson; *Editor*, Mr. J. H. Calaby; *Council Members*, Dr. A. K. Lee and Dr. A. G. Lyne.

The Night Sky in September

New moon occurs on Sept. 10d. 02h. 50m. U.T. and full moon on Sept. 24d. 11h. 34m. The following conjunctions with the Moon take place: Sept. 1d. 23h., Aldebaran 0·3° S.; Sept. 7d. 00h., Venus 2° N.; Sept. 19d. 22h., Saturn 3° S.; Sept. 20h. 05m., Jupiter 3° S.; Sept. 29d. 07h., Aldebaran 0·4° S. In addition to these conjunctions with the Moon, Mars is in conjunction with Spica on Sept. 20d. 11h., Mars being 2° S., Mercury with Spica on Sept. 21d. 12h., Mercury being 0·1° N., Mercury with Mars on Sept. 22d. 21h., Mercury being 3° S., and Venus with Regulus on Sept. 22d. 23h., Venus being 0·4° N. Mercury is too close to the Sun for observation. Venus is a morning star, rising at 1h. 50m., 2h. 30m. and 3h. 10m. on September 1, 15 and 30, respectively. Its stellar magnitude on September 15 is – 3·4; the visible portion of the apparent disk increases during the month from 0·792 to 0·870 and its distance from the Earth increases from 115 to 131 million miles. Mars is too close to the Sun for observation. Jupiter is an evening star, setting at 1h. 30m., 0h. 30m. and 23h. 30m. on Sept. 1, 15 and 30, respectively. It is in Capricornus; its stellar magnitude on Sept. 15 is – 2·2, and its distance from the Earth is 410 million miles. Saturn is an evening star, setting at 1h. 10m., 0h. 10m. and 23h. 10m. at the beginning, middle and end of the month, respectively. It is in Sagittarius; its stellar magnitude is + 0·6 on Sept. 15 and its distance from the Earth is 880 million miles. Occultations of stars brighter than magnitude 6 are as follows, observations being made at Greenwich: Sept. 1d. 23h. 46·7m., σ^3 Tau. (*R*); Sept. 16d. 19h. 54·7m., 24 Sco. (*D*); Sept. 26d. 21h. 25·6m., ξ^2 Cet. (*D*); Sept. 26d. 22h. 19·6m., ξ^2 Cet. (*R*); Sept. 28d. 1h. 40·4m., 5 Tau. (*D*); Sept. 28d. 2h. 46·6m., 5 Tau. (*R*); Sept. 28d. 22h. 50·1m., γ Tau. (*D*); Sept. 28d. 23h. 43·0m., γ Tau. (*R*); Sept. 29d. 3h. 32·9m., θ^1 Tau. (*D*); Sept. 29d. 3h. 45·1m., θ^2 Tau. (*D*); Sept. 29d. 4h. 30·6m., θ^2 Tau. (*R*); Sept. 29d. 4h. 43·2m., θ^1 Tau. (*R*); Sept. 29d. 7h. 57·7m., α Tau. (*D*); Sept. 29d. 8h. 53·8m., α Tau. (*R*). *D* and *R* refer to disappearance and reappearance, respectively. The autumnal equinox occurs on Sept. 23d. 07h.

Announcements

Dr. L. R. G. Treloar, of the Shirley Institute, Manchester, has been awarded the Colwyn Medal of the Institution of the Rubber Industry. Mr. M. M. Heywood, director of P. D. Cow and Co., Ltd., has been awarded the Institution's Hancock Medal.

A symposium on "Forest Ecosystem" (definitions and classification of forest ecosystem) was held in Montreal in 1959 under the auspices of the Ninth International Botanical Congress. Dr. I. Hustich of Finland was chairman and organizer for the symposium. The papers have now been published in full in a special issue of the *Bulletin of the International Society for Tropical Ecology*. Copies can be had from Dr. G. S. Puri, General Secretary, International Society for Tropical Ecology, 10-Chatham Lines, Allahabad, India (price Rs. 25, £2, 6.00 dollars).

The Chemical Society is arranging a symposium on electron spin resonance, which will be held in Queen Mary College, London, on November 2. Further information can be obtained from the Secretary, Chemical Society, Burlington House, London, W.1.

The annual Pittsburgh Diffraction Conference will be held at the Mellon Institute, Pittsburgh, Pennsylvania, during November 1–3. Further information can be obtained from T. B. Massalski, Mellon Institute, 4400 Fifth Avenue, Pittsburgh 13, Pennsylvania.

The Universities Federation for Animal Welfare (UFAW) will hold its annual Summer Congress at Shipham, Winscombe, Somerset, during September 16–23, 1961. Further information can be obtained from UFAW (Summer Congress), 7a Lamb's Conduit Passage, London, W.C.1.

The Borough Polytechnic, London, is organizing a course of six lectures on "The Technique of Technical Writing". The lectures will be given on Friday afternoons commencing October 20. Further information can be obtained from the Secretary, Borough Polytechnic, Borough Road, London, S.E.1.

A meeting of the British Pharmaceutical Conference will be held at Portsmouth during September 18–22. To be included in the programme is a lecture by Dr. A. Isaacs on "Interferon" and a symposium on "Skin Medication". Further information can be obtained from the secretary, British Pharmaceutical Conference, 17 Bloomsbury Square, London, W.C.1.

The Food Group of the Society of Chemical Industry is organizing a symposium on "Recent Advances in Processing Cereals" at the Royal Society of Medicine, London, during September 14–15. Further information can be obtained from the Assistant Secretary, Society of Chemical Industry, 14 Belgrave Square, London, S.W.1.

An international symposium on "Photoelasticity" will be held at the Illinois Institute of Technology, Chicago, Illinois, during October 29–31. The symposium will consist of five sessions including: birefringent coatings; photothermoelasticity and photoplasticity; two- and three-dimensional photoelasticity; dynamic photoelasticity and three-dimensional photoelasticity. Further information can be obtained from Prof. M. M. Frocht, chairman of the International Symposium on Photoelasticity, Department of Mechanics, Illinois Institute of Technology, Technology Center, Chicago, 16.

Erratum. In the communication entitled "Effects of Injections of Some Intermediary Metabolites on the 'Insulin Response' of Normal Rabbits", which appeared in the issue of July 29, p. 491, for "trichloroacetic" on line 9 read "tricarboxylic".

THE CARNEGIE UNITED KINGDOM TRUST

THE forty-seventh annual report of the Carnegie United Kingdom Trust covers the year 1960, but also includes a review of the quinquennium 1956–60, in which grants-in-aid of £525,881 brought the total expenditure of the Trust since it was founded in 1913 to more than £6 million*.

Apart from grants which are virtually subscriptions to national bodies and which in 1961–65 will comprise only the National Councils of Social Service in England, Scotland, Wales and Northern Ireland, and Foras Eireann in the Republic of Ireland, the Trust's grants fall into two main categories: those used to finance special inquiries and experiments, and those which provide a wide range of equipment and services. The first category gives the Trust scope to support innovation and pioneering in the arts, in social services and in education, but during the past quinquennium the largest proportion of grant-aid has gone to beneficiaries in the second category, particularly for the re-equipment of village halls and for museums. During the quinquennium, grants for the arts accounted for 11·72 per cent, for community services for 56·58 per cent, physical and mental welfare for 6·99 per cent, education for 15·5 per cent, youth services for 0·62 per cent, and nature reserves and parks for 8·59 per cent, the last including a grant for the David Marshall Lodge, Aberfoyle, opened in 1960, in the Queen Elizabeth Forest Park, and a sum of £50,000 has been allocated for the provision of other suitable amenities in such special areas during the 1961–65 quinquennium, out of a total allocation of £416,500. Other allocations for 1961–65 include £45,000 for museums, £100,000 for new communities, £100,000 for youth service and £10,000 for field studies, which will cover grants for projects approved and recommended by the Council for British Archæology and by the Council for Nature, both for field work in natural history and for Conservation Corps projects.

During 1960 the Trust continued its policy of assisting the development of museums and their associated art galleries, and 16 museums were offered grants for modernizing their displays; but the Trust does not consider that the museum service generally receives the support it deserves, though it is watching with interest certain developments which promise to deal with the situation. During the quinquennium, grants amounting to £49,930 brought the total aid from the Trust during 30 years to nearly £150,000, not including £16,695 promised to 38 museums towards expenditure on reorganizing displayed collections and a special grant of £1,000 to the Royal Burgh of Culross for work on an attractive old building, "The Study", which the National Trust for Scotland has restored for use partly for residential purposes, partly as a small museum and partly as an information centre, and another of £10,000 towards the capital cost of a Shetland Museum and Art Gallery at Lerwick. For the next quinquennium, the Trust's grants for museums will continue to be devoted largely to encouraging modernization of displays.

Although the last quinquennial report recorded the completion of the Trust's policy of grant-aid for the building or adaptation of village halls in the United Kingdom, an inquiry in 1956 convinced the Trustees that there were needs not being met from public funds, and they decided to return to this field with an allocation of £100,000 for grants for refurnishing and re-equipping pre-war halls in villages of not more than 1,000 people. By the end of 1960 some 1,636 applications had been received and the allocation increased to £200,000. During 1960 promises numbering 216 brought the total to 1,267 and the commitment to £171,031. Two more schemes for film projectors in the Highlands were approved on the recommendation of the Highlands and Islands Film Guild and a set of equipment is being presented to the people living on the Skerries, off the coast of Shetland. The social problems of new communities have received special attention during the quinquennium, and a report by Dr. J. H. Nicholson on his study of four types of new community is being published this year under the title "New Communities in Britain: Achievements and Problems". The £100,000 allocated for grants in this field will be available for projects that are truly pioneer, and likely to serve as prototypes, if successful; a grant of £12,000 has already been promised for the building of the Family Welfare Centre of the Kirkby Council of Social Service, and a tapering grant of £3,000 over 5 years to Hartcliffe Community House, Bristol, for provision of a warden and a qualified social worker.

A grant of £1,000 was made to Gates Youth Club, Crawley, to assist in building a permanent youth club and one of £8,000 to Edinburgh University Settlement for the erection of a multi-purpose building to serve primarily as a youth centre and also as a training ground for youth leaders. The Trust has also promised half the total cost of £13,000 required to establish the Northern Ireland Association for Mental Health for its first five years, and a supplementary grant of £3,500 was offered to the National Association for the Paralysed, for connecting to mains drainage several buildings at Dorincourt for work among the young chronic sick. £5,000 on a £1 for £1 basis after the first £10,000 was assured was offered to the Edinburgh Cripple Aid Society for a scheme to cost £20,000 for establishing an up-to-date centre for all physically handicapped persons who require assistance, and a grant of £2,250 was promised to the Y.W.C.A. for the salary and expenses of a part-time research assistant, to work for three years under supervision from the head of the Social Science Department, London School of Economics, for an experiment in social work among adolescents based on a coffee bar in the Paddington area of London.

During 1960, 120 students from 75 local scientific societies received bursaries to attend residential courses in botany, zoology, geology, ecology, archæology and related subjects at a cost of £360, and 17 grants, totalling £1,091, were made for field work in archæology. Nine courses for instruction of amateurs in meteorology were arranged, five of which were vacation courses at the Field Study Centres of Malham Tarn, Preston Montfort and Dale Fort, and three week-end courses at Lasham, Longmynd and Dunstable. Grants for youth service in the new quinquennium will be substantially for refurbishing and improving existing youth clubs. A grant of £12,750 payable over 5 years from the beginning of 1960 has been promised to the Central Council for the Care of Cripples to establish and develop the Homecrafts Advisory Association for the Disabled.

---

* The Carnegie United Kingdom Trust. 47th Annual Report, 1960. Pp. viii+98. (Dunfermline, Fife: The Carnegie United Kingdom Trust, 1961.)

THE REGIONAL RESEARCH LABORATORY, HYDERABAD

THE annual report for 1959–60* of the Regional Research Laboratory, Hyderabad, is a substantial attractively produced volume printed on hand-made paper manufactured by the Laboratory. It includes lists of research staff, auxiliary technical staff and administrators' staff and of publications and patents, and gives fairly full details of research projects in progress. Most of the projects relate to some industrial process or product, but increasing emphasis is laid on the fundamental aspects of applied problems. A Specialists' Committee, under the chairmanship of Prof. M. S. Thacker, has been appointed to examine the research programmes and make recommendations broadly on the future scope of the research programmes undertaken by the Laboratory.

The work of the Laboratory continues to range over a wide field. In oils and fats, the keeping quality of castor oil and cottonseed oil claimed much attention, as well as the preparation of derivatives. A series of programmes on surface coatings dealt with dehydrated castor oil, its isomerization and styrenation, and the preparation of varnishes from dehydrated castor oil, as well as the preparation of alkyds, emulsion paints, the weathering of paints and the use of cashewnut shell liquid. Syntheses in the quinoline, isoquinoline and thieno-pyrimidine series were directed to the preparation of compounds of potential pharmacological interest, while a process for the manufacture of phenylacetic acid was re-examined, and 8-hydroxyquinoline and 5-chloro-7-iodo-8-hydroxyquinoline synthesized for treatment of amœbic dysentery. Schemes relating to essential oils and aromatic chemicals deal with palmarosa oil, Indian cinnamon leaf oil and the utilization of Indian turpentine. In addition to entomological work on insecticides, investigations have been carried out on the effect of X-rays on the biological and biochemical characteristics of the spermatozoa of insects.

In biochemistry, the microbiological production of calcium and ferrous gluconate and of citric acid, the effect of cell concentration on the biological properties of individual cells in cell suspensions, and the biosynthesis and metabolism of proteins and nucleic acids have been examined. Programmes dealing with fuel cover the low-temperature carbonization of non-caking Indian coals and the utilization of products of the low-temperature carbonization of coal. Activated carbons and bleaching earths continue to receive attention, and there are programmes dealing with titanium pigments, the manufacture of white cement from felspar and the preparation of catalysts for the low-pressure hydrogenation of tar. Physico-chemical investigations dealt with the mineralogical composition of the bleaching earths, spectro-photometric work on tar acids from low-temperature carbonization, the surface properties and heat of wetting of absorbents and catalysts.

Under chemical engineering is included work on the vapour–liquid equilibrium of fatty acids and tar acids; the fluidized activation of carbon; pilot plant production of lævulinic acid and lounginin (a synthetic flavouring agent); and pilot-plant investigations in the milling of cotton seed and castor seed.

---

BIORHEOLOGY AND MICROCIRCULATION

FOLLOWING a reception at the Hadassah Visitors' Club, a seminar on biorheology and microcirculation was opened on April 24 at the Medical School, Jerusalem, by Dr. K. J. Mann, the general director of Hadassah, and delegates were also welcomed by Prof. M. Rachmilewitz, dean of the medical school, Hebrew University.

Dr. E. Davis (Jerusalem) introduced the symposium with a paper on the general nature and problems of microcirculation as studied by optical and electron microscopy. A main problem is how the capillaries change in diameter—whether passively in response to changes in blood content, or actively in response to nervous or chemical stimuli. How red cells pass through the apparently intact capillary is also still a mystery, nor are the spontaneous changes in calibre and rate of flow of blood in the small vessels understood.

Introducing the biorheological aspect, Dr. G. W. Scott Blair (Reading, England) outlined briefly the history of the application of rheology, "the study of the deformation and flow of matter", to biological systems. Poiseuille, a pioneer of rheology, and Bingham, who named this branch of physics and organized the first society of rheologists, both worked on problems of blood-flow. Biorheologists now study many other systems, such as muscle, protoplasm, cervical mucus, synovial fluids, bronchial mucus, intraocular and cerebrospinal fluids, strength of bones, etc.

Dr. H. Harders (Hamburg, Germany) stressed the technical difficulties involved in direct microscopic observations of microcirculation *in vivo*. But the importance of such studies is undisputed. Many diseases have microcirculatory aspects, and some, such as sickle-cell disease, cold hæmagglutination syndrome, polycythæmia and hæmorrhagic thrombocythæmia, are primarily disturbances of microcirculation. The influence of vaso-active drugs and of smoking can be studied by microscopic examination of capillaries. Dr. Harders concluded by predicting that microvascular observations would, in future, play an essential part in routine examinations.

Dr. J. W. Irwin (Boston, Massachusetts) showed, with a film, the pulmonary microcirculation in the living rabbit. The arterioles, capillaries and venules could be seen, and the pulsating flow was readily observed. Pharmacological reactions were also demonstrated. A capacitance electromanometer was shown which could be used, provided that the tip of the microcannula was less than 20μ in diameter, but a more efficient manometer would be needed if true capillary pressures were to be studied.

Dr. J. Weinman and Dr. M. Manoach (Jerusalem) described photoelectric techniques for studying the peripheral circulation in man. Living tissue is transparent to those wave-lengths of red and infrared radiation at which measurements of extinction coefficients of blood are generally made. Quite cheap incandescent lamps and photoconducting cells may be used as radiation sources and detectors to follow pulsating flow of blood and vasomotor action. Photocells and light sources are combined in a small unit, attachable to any part of the body. Such stimuli as postural gravitational changes and smoking may be studied in this way.

The last session at Jerusalem was opened by Prof. A. Katchalsky (Rehovot), who described differences in osmotic fragility under normal and gradual conditions of hæmolysis. Under normal hæmolysis, stresses develop rapidly and rupture the cell membrane. Under slow hæmolysis a higher hypotonicity is required. The membrane behaves as a Kelvin body with a characteristic retardation time. Dr. D. Danon (Rehovot) showed two phase-contrast microcine films illustrating deformation, shearing and hæmolysis of normal human erythrocytes under gradually decreasing salt concentration. Mixed ion exchangers and also dialysis through a 'Cellophane' membrane were used to reduce salt concentrations. Dr. G. Segré and Dr. A. Silberberg (Rehovot) studied the radial distribution of rigid macroscopic spheres in a Poiseuille field of flow, showing that particles undergo a sideways displacement, both from the centre outwards and from the tube wall inwards. Although these results should be applied with caution to flow of blood, M. G. Taylor, scanning a capillary optically and measuring absorption along a diameter, has shown a similar 'tubular pinch' effect.

The second part of the programme, held at the Weizmann Institute of Science, Rehovot, opened with a paper by Dr. S. Lazarus, Dr. H. N. Munro and Dr. G. H. Bell (Glasgow) on capillary strength tests in scurvy and their reactions to vitamins C and P therapy. Both positive and negative pressure tests were used on three small groups of subjects of about the same age: (1) fifteen cases of scurvy; (2) twenty-nine hospital in-patients without scurvy; and (3) twenty well-nourished hospital visitors. Negative pressure tests were inconcuslive, but positive pressure tests showed some weakness in the capillaries of scurvy patients, though more than a quarter of them fell within the normal range of group (3) subjects. Treatment with vitamins C and P did not increase capillary strength. The authors tentatively suggested that it was not scurvy which produces capillary weakness, but that subjects with already weak capillaries are perhaps more prone to develop scurvy.

Dr. S. Ben Hador, Dr. E. Davis, Dr. J. Landau and Dr. M. Ivri (Jerusalem) discussed the effect of adrenaline on the small blood vessels of the conjunctiva and nailfold, concluding that these vessels are more sensitive to adrenaline in the presence of hypertension than when blood pressure is normal. As an example of the results presented: injecting 0·4 mgm. adrenaline produced severe thinning in the small vessels of the nailfold in two of seven healthy subjects, and appreciable thinning in two more cases; whereas, among eleven hypertensives, severe thinning appeared in six, and appreciable thinning in five, cases. Among ten arteriosclerotics, there was no severe thinning and there were six cases of appreciable thinning.

Dr. J. W. Irwin (Boston, Massachusetts) discussed microcirculation of the inner ear, and showed a film demonstrating this in living guinea pigs. A remarkable and unexplained finding is that the chemical components of endolymph and perilymph, which the author considered as part of the circulation of the inner ear, appear to differ, although these fluids are separated in one area only by a two-cell thick membrane (Reissner's membrane).

Dr. E. Davis, Dr. S. Ben Hador, Dr. J. Landau and Dr. M. Ivri (Jerusalem) then described observations and experiments on vasomotion in human capillaries. The number of spontaneous changes a minute in calibre or velocity of blood-flow in capillaries is defined as the 'vasomotor count'. In healthy subjects and in arteriosclerotics, the vasomotor count lies normally between 0 and 14, but in hypertension and in diabetes mellitus, two-thirds of the cases showed values greater than 14. Injections of 0·4 mgm. adrenaline showed no change in vasomotor count in healthy subjects, but increases in 7 out of 11 cases of hypertension and also 3 out of 9 arteriosclerotics. The increased vasomotion of hypertension may reflect increased sensitivity to adrenaline.

In the final paper, Dr. G. W. Scott Blair (Reading, England) briefly outlined the history of rheological theory, from Hooke's law of elasticity (stored energy) and Newton's concept of viscous flow (dissipated energy) to modern theories of entropy-high elasticity. Living organisms maintain themselves by preventing fatal rises in entropy through drawing 'negative entropy' from their surroundings. In a steady, as distinct from a static, state a system undergoing an irreversible process requires a rate of increase of entropy having the minimum possible value consistent with external conditions. Dr. Scott Blair predicted that it is along the lines of Onsager and Prigogine's 'irreversible thermodynamics' that rheological theory must develop if it is to deal with studies of living systems.

Prof. M. Reiner (Haifa), who presided at one of the sessions, discussed the function of models in biorheology and, in a final general discussion, views were expressed concerning the future international organization of biorheology, especially the part which might be played by the new international journal *Biorheology*, shortly to appear.

Apart from the technical sessions, there were many pleasant social activities at which the traditional Israeli hospitality was seen to its full advantage.

G. W. SCOTT BLAIR

PAPER CHROMATOGRAPHY

THE technique of paper chromatography was first described by Consden, Gordon and Martin in 1944. In 1948, Dr. Gordon was invited to Czechoslovakia for a year to set up and teach this technique. Since that time the work of the Czech Schools has become more and more important in this field and there can be little doubt that, at present, the work of Drs. I. M. Hais, K. Macek, C. Michalec and their co-workers is among the most important of the systematic and general research in paper chromatography. So far as we are aware, the Czech Chemical Society is the only chemical society which has a Chromatography Group, and it is therefore not surprising that it should have organized a conference on the subject of paper chromatography during July 21–24, 1961.

The conference, using Czech, English and German as official languages, was organized so that the first two days were given to the discussion of new techniques, reviews of particular fields, papers relating chromatographic behaviour to chemical and physical properties and to the paper chromatography of lipids—a subject to which the Czechs have devoted a very great deal of time—and the third day to a discussion of theoretical and practical problems. As many papers were read in Czech, books containing adequate summaries in various languages were handed to each participant in advance and interpreters were assigned to individual national groups. The first two days were considered as open days, and students and others interested were encouraged to attend. The third day was arranged as a closed meeting confined to about sixty participants, which was held in a hall with radio equipment and transistorized headphones on which were relayed simultaneous translations in English, German and Russian. For this the participants were transported to a small castle outside Prague which the Government has made available to the National Academy of Sciences as a holiday resort for scientists.

In the introductory review, Dr. R. Consden discussed briefly the origin and development of paper chromatography and went on to a consideration of the various new papers, now becoming available, and new techniques, such as centrifugal field methods. Other speakers then reviewed particular subjects. Thus Dr. C. Knight of Balston, Ltd. (Whatman filter papers), spoke on the new ion exchange papers in which the active exchange group is built into the cellulose molecule. He described the cation exchangers such as cellulose–phosphate and citrate and carboxymethylcellulose, together with their application to the separation of amino-acids and cations in general and followed with a similar discussion on the cellulosic anion exchangers including diethylaminoethyl cellulose. Similar papers were also discussed by Dr. Grüne, of Schleicher and Schüll, who went on to consider the value of new types of paper which have alumina or silica gel incorporated into the cellulose matrix at the manufacturing stage. She pointed out that these papers function as micro alumina or silica gel columns and yield results similar to the classical column procedures. They are thus useful for the examination of new solvents for column chromatography as well as for separations in their own right. Among many examples quoted we may mention only the separation of carotenoids and chlorophylls on these papers.

There followed reviews on the separation of particular families of compounds and a few may be taken for special comment. Dr. F. H. Pollard gave an interesting review of present work and advances in the inorganic field. In particular, the search for new general and specific location reagents and for faster solvents had been quite successful. In a second paper he described a method for the rapid systematic analysis of some twenty-four cations using a single solvent in conjunction with a large number of reagents for location and confirmation of identity. This method had been used most successfully by students in place of the classical inorganic group separations. Results of Australian workers in the inorganic field were discussed by Dr. M. Lederer. An excellent review of the chromatographic separation of some two hundred alkaloids on formamide-treated paper was given by Dr. D. Waldi (Germany), who directed attention to the possible errors due to variation in the formamide itself.

One whole session of the conference was devoted to the paper chromatography of fatty acids, esters and related compounds. Following a comprehensive review by Dr. Michalec on solvents, reagents and techniques useful in this field, other papers discussed particular series of compounds. Methods were described for the separation of *cis–trans*-isomers of the acids together with the application of this work in the determination of the mechanics of catalytic hydrogenation. Other speakers dealt with the use of coated papers, such as formamide or dimethylformamide-treated papers, for the separation of free fatty acids or their urea adducts, and the quantitative methods available for esters, glycerides, etc.

The only paper devoted to the theory of paper chromatography was that of Prof. V. V. Racinskij (U.S.S.R.), who discussed chromatographic separation in terms of the general theory of sorption dynamics. Like other theories, this theory requires the measurement of the cross-sectional areas of both phases on the paper. However, as it has not yet been found possible to determine these areas, we must agree with Prof. Racinskij himself, who concluded by directing attention to the lack of applicability of these calculations and theories to everyday paper chromatography.

Two films were shown near the beginning of the meeting. One entitled "Principles of Chromatography", by Drs. J. B. Jepson and I. Smith, illustrated the general procedures and techniques of paper and column chromatography, while the second, by Drs. V. Holeysovsky, V. Tomasek, K. Kochloefl and K. Setinek, was a complete description of the "Technique of Paper Chromatography of Amino-acids" as carried out in Prague. Taken together they formed a suitable introduction to the conference for the many students present. While the British film is available on loan or sale it is regrettable that the Czech film is not.

The original intention for the closed meeting on the third day was to have a symposium on the relationships between chemical structure and chromatographic behaviour in the morning followed by a symposium on systematic analysis in the afternoon. In a sense, the whole three days were devoted to these topics;

but, despite the very long hours put in each day, there was insufficient time for adequate and fruitful discussions.

The main discussion at the two symposia, at which Prof. Marini-Bettolo (Italy) presided, centred around the papers of Drs. Hais and Macek, and included contributions by Drs. Consden, Smith, Waldi, Racinskij and others. They emphasized the fact that the vast amount of chromatographic data in the literature was not being used to the full simply because of the lack of standardization of apparatus, methods, reagents, etc., and that this rendered comparisons and deductions between the results of different workers dangerous. They directed attention to the very wide and detailed systematic studies of Dr. I. Smith in the biochemical field and to the limited number of such studies in other fields. We were interested to learn that the Soviet Union does not produce a single piece of apparatus which is primarily intended for paper chromatography. The variety of types of apparatus used by workers in different countries is unfortunately manifold. Because of these differences it is not yet possible to correlate the data produced in different laboratories on anything like the scale which would be desirable. This is regrettable, as there can be no doubt that standardized and correlated data would be valuable in avoiding the present duplication and reduplication of labour. Moreover, far more important than this, standardized data could be used on electronic data processing machines based on suitable punched-card systems. Furthermore, the availability of such standardized data would be valuable for the determination of various other chromatographic data, such as R_m values, and for the correlation of such properties with other physicochemical measurements. This in turn might lead to a type of structural analysis based on the splitting of R_F and R_m values into functional group constants with the possible application of physical-organic chemistry to the general problems of paper chromatography. This latter point was discussed at some length by Ing. Prochazka and Ing. Gasparic. The Czech Chemical Society has attempted with some success to standardize methods in its own country and, in spite of difficulties, Drs. Macek and Hais have gone ahead and devised their own punched-card system suitable for machine operation. No doubt we can look forward to more interesting developments from their laboratories.

Participants were shown around two laboratories. Dr. Macek conducted a tour of the Pharmaceutical and Biochemical Research Institute, which is well equipped to study all aspects of paper chromatography, including the data-correlation problem. This was followed by a tour of the Institute of Organic Chemistry and Biochemistry of the Czechoslovak Academy of Science, led by Prof. B. Keil. The main problem of Dr. Keil and his team is the amino-acid sequence of chymotrypsinogen and the laboratory is extremely well equipped for this purpose. The electronic data sorting approach to the study of overlapping sequences, etc., is also in an advanced stage. We are interested to note the close collaboration between this team and others in the United States working on the same problems.

FOREST PRODUCTS RESEARCH IN BRITAIN

THE extreme complexity of the principal product of the forest, timber, is well exemplified by the very varied contents of the report for 1960 of the Director of Forest Products Research*. In it reference is made to research into wood structure, wood seasoning, bending, mechanics and other properties of timber. Sections are devoted to woodworking, wood preservation and to the study of the fungi and insects which batten on timber. The chemistry and physics of timber are receiving attention and in this connexion surely more attention should be given to the chemistry of those timbers of trees which from a sylvicultural point of view ought to be much more widely grown, especially in England, than they are—namely, oak, birch, alder and other leaf-trees. It would be very helpful if timbers containing substances which are a nuisance in paper-making, but which might furnish materials for other uses, could be enhanced in value and grown more profitably. Recent progress in Japan is of interest.

The close association of the Forest Products Research Laboratory with the Forestry Commission no doubt accounts for the prominence given in the research programme to Sitka spruce and what is loosely called "Lodgepole pine". The former has been very extensively planted and the latter, after a period of neglect, is now also much in favour. Both are useful trees, and it is certainly important that everything should be done to justify their being grown, but surely not at the expense of work on other sylviculturally more useful trees with no less valuable timber. The Republic of Ireland, where the utility of *Pinus contorta* Doug. was appreciated earlier than in Great Britain, is indeed fortunate in being able to make use of the Laboratory, while the latter is fortunate in being able to obtain research material from abroad suited to its needs.

An investigation just completed into the strength and specific gravity of Sitka spruce grown in Great Britain proves fairly conclusively that the method of site classification adopted by the Forestry Commission is at fault. The samples tested were chosen from six geographical regions corresponding to 'Districts' of the Meteorological Office, in other words, climatic regions, and within these the stands of trees, whence the samples came, were classified into five groups based on rate of growth in height, called, unfortunately, quality-classes, but really productivity-classes. The interesting result of this investigation was to find no significant differences among the six climatic regions, nor among the productivity-classes as a whole, but that differences in quality tend to arise more from individual site factors. It thus seems that rate of growth is not a sound basis of site classification for this kind of work, as most foresters realize. A better classification is one based on the factors of geology and the availability to the trees of nutrients and soil moisture. It would be valuable to have the work repeated or the existing data re-analysed on such a basis.

---

* Department of Scientific and Industrial Research. *Forest Products Research 1960*: Report of the Products Research Steering Committee with the Report of the Director of Forest Products Research. Pp. v+60+8 plates. (London: H.M.S.O., 1961.) 5s. net.

The report does not say specifically what the value of the timber of *Pinus contorta* Doug. is compared with that of other trees, information which would be of the utmost importance to the forester. The structure of its wood is said to be intermediate between, for example, yellow pine and Scots pine. There is some slackness in nomenclature in the report; apart from leaving one in doubt about what yellow pine is, the terms 'redwood' and 'whitewood' are still used with no explanation that the former is wood of Scots pine and the latter that of Norway spruce. The laboratory should think of the grower as well as of the user.

It is almost certain that timbers will long remain among the most useful of raw materials, and the more we can learn about them the better. As the chairman of the Forest Products Research Steering Committee in his introduction says, there is no lack of work to be done, but why is all the work kept in the south of Britain ? Some could be done just as well at a properly equipped laboratory in the north. The Committee has a difficult task in avoiding the many reefs and in selecting the most profitable waters. The greater attention now being given to home- (and Irish-) grown timbers is, however, likely to be fully justified.

M. L. ANDERSON

DRUG SUPPLIES DURING THE AMERICAN REVOLUTION

INITIALLY, drug supplies for the American Revolutionary Army came from stocks largely in the hands of private druggists. This source of supply was totally inadequate for a war that attained such proportions as the Revolution. Even if stocks of drugs in the Colonies had been far greater than they were, there is little reason for believing that shortages would not have developed. Even the most patriotic pharmacists were faced with complete financial suicide, caught between a spiralling inflation and a Congress that had no money and only a promise for the future. In an interesting paper, George B. Griffenhagen, formerly curator of medical sciences, U.S. National Museum, Smithsonian Institution (*Bull.* 225), shows how the internal organization of the medical department of the army was so chaotic that, even if adequate supplies were available and if the almost unsurmountable problems of communications and transportation had been solved, it is almost certain that shortages would have developed at least during the campaign of 1776.

The encouragement which Congress, through its Secret Committee, gave to private shippers for the importation of vital war supplies offered little relief in the field of medical supplies. Importation was cut off from Great Britain, and France did not directly export any quantities of medical supplies, at least until 1778. American privateers found it much more profitable to prey on British shipping than to develop trade channels with countries which, prior to the Revolution, were prohibited from shipping directly to the Colonies.

Hence, the most immediate relief from medical supply shortages was provided by the American privateers. Drug cargoes from British prize ships, many of which were en route to New York, served as a most important source of supply, particularly during 1777 and 1778.

The number of individual drugs mentioned in various inventories was considerable. Of these, only about a dozen were critically short. Heading the list of these 'capital articles' was Peruvian bark, the same cinchona from which quinine was later discovered. Tons of bark were used during the Revolutionary War, and the price more than quadrupled between June 1776 and September 1777.

The most prominent group of drugs on the list of capital articles consisted of cathartics and purgatives. Jalap, ipecac, and rhubarb were the botanical favourites, while bitter purging salt (Epsom salts) and Glauber's purging salts were the chemical choices for purging. Tartar emetic was the choice for a vomit, and cantharides (Spanish flies) was the most important ingredient for blistering plasters. Opium was administered for its narcotic effects, while gum camphor, nitre (saltpetre or potassium nitrate), and mercury (pure metal as well as certain salts) were employed for a variety of purposes. Lint, a form of absorbent material made by scraping or picking apart old woven material, was also in short supply.

Equipment shortages included surgical instruments and mortar, and pestles for pulverizing crude drugs. Glass vials for holding compounded medicines were also a supply problem, especially after essential drugs again became available. Some of the shortages were eased by local manufacture. Lint was produced in large quantities in the Colonies, and glass vials were manufactured in numerous glasshouses. Local manufacture of purging salts and nitre aided in eliminating shortages of these essential items, and, at the same time led to the first large-scale pharmaceutical manufacturing in the United States.

π-ELECTRONIC EXCITATION AND IONIZATION ENERGIES OF CONDENSED RING AROMATIC HYDROCARBONS

By DR. J. B. BIRKS and M. A. SLIFKIN

Physical Laboratories, University of Manchester

THE condensed ring aromatic hydrocarbons form an interesting group of molecules. They possess delocalized π-electron systems, loosely bound by a potential defined by the shape of the planar molecular skeleton; they scintillate, fluoresce and phosphoresce; some of the higher members are carcinogenic; and they possess certain well-defined electronic energy-levels which vary systematically with molecular size. They have been the subject of many theoretical studies, including those based on the molecular orbital[1-3], valence-bond, and free-electron[4] models. These have led to the classification and computation of the π-electronic energy-levels in many of the simpler compounds, although because of the complexity of the many-electron systems and the resultant interactions it is normally necessary to introduce arbitrary parameters to achieve reasonable agreement with the experimental data.

The electronic ground-state S_0 of the molecules is singlet, and analysis of the visible and ultra-violet absorption spectra ($S_0 \rightarrow S_n$) of vapours or dilute solutions yields direct information on the singlet π-excitation energy-levels S_n. Complementary data on the energy and life-time of the first singlet excitation state S_1 are obtained from studies of the molecular fluorescence emission, $S_1 \rightarrow S_0$.

The triplet π-excitation energy-levels are less amenable experimentally, since singlet-triplet absorption transitions are normally forbidden. The first triplet π-excitation energy T_1 can be obtained from observations of the low-temperature phosphorescence emission ($T_1 \rightarrow S_0$) of glassy solutions[5], or by the solvent perturbation technique[6] which allows the $S_0 \rightarrow T_1$ transition to be observed in absorption at room temperature. Higher triplet states have been observed in transient $T_1 \rightarrow T_n$ absorption transitions, using the flash photolysis method[7].

The ionization energies of a few of the smaller molecules and their derivatives have been obtained directly from photo-ionization measurements[8], electron impact studies[9] and vacuum ultra-violet Rydberg spectra[10] of the vapours. These methods are not applicable to the heavier, less volatile compounds, and an indirect technique[11,12], involving the measurement of the absorption spectra of the charge-transfer complexes formed by the compounds with an electron acceptor in solution, has been used to obtain the ionization energy I of the molecules.

In this article data are presented on I, T_1 and S_1 for 18 condensed ring aromatic hydrocarbons and for 10 methyl derivatives of 1 : 2-benzanthracene. The latter were included in the study in order to increase the number of carcinogenic hydrocarbons considered.

The energy E_{CT} of maximum absorption of the charge-transfer band of the complex with chloranil in carbon tetrachloride solution has been observed for each compound. Similar measurements on some of the compounds have been reported by previous observers[11,13]. Our values agree closely with these, except in the case of tetracene and chrysene, where they confirm the values of Briegleb and Czekalla[11], but are less by 0·11 eV. and 0·23 eV. respectively than those of Peticolas[13]. I has been evaluated from the linear relation established by Foster[12] from observations on compounds of known I, namely:

$$I = 5{\cdot}13 + 1{\cdot}12\,E_{CT} \quad \text{(eV.)} \qquad (1)$$

Table 1. CONDENSED RING AROMATIC HYDROCARBONS

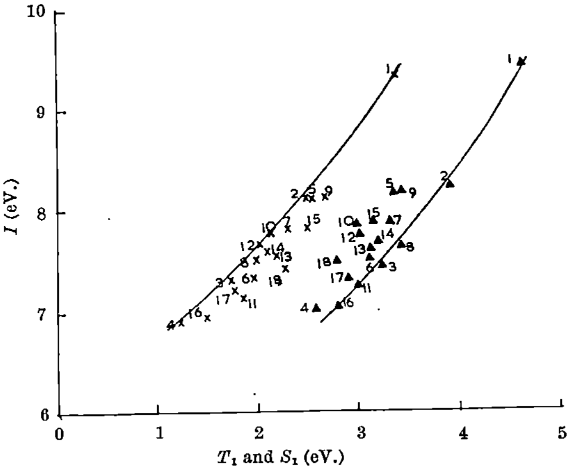

Fig. 1. Condensed ring aromatic hydrocarbons. T_1 (×) and S_1 (▲) against I

The triplet energy T_1 of seven of the compounds has been measured by the solvent perturbation technique[6] using oxygen under high pressure. The oxygen forms a contact charge-transfer complex with the hydrocarbon, and the absorption spectrum corresponding to the $S_0 \rightarrow T_1$ transition is observed superposed on the charge-transfer band. Values of T_1 for the other compounds have been obtained from the data of other observers who used solvent perturbation[6,14] or phosphorescence spectrometry[15-17]. Values of S_1 have been obtained from the solution absorption spectra[18,19].

The results are presented in Tables 1 and 2.

Table 2. METHYL DERIVATIVES OF 1:2-BENZANTHRACENE (Energies in eV.)

	E_{CT}	I	T_1 (ref.17)	S_1	$\overline{E}_1$	Carcinogenicity
1:2-Benzanthracene	2·06	7·45	2·05	3·22	2·63	+
2′-Methyl	2·02	7·39	2·06	3·22	2·64	
3′-Methyl	2·05	7·43	2·07	3·23	2·65	
4′-Methyl	2·05	7·43	2·07	3·20	2·63	
3-Methyl	2·05	7·43	2·08	3·20	2·64	+ +
4-Methyl	2·03	7·41	2·10	3·23	2·66	+ +
5-Methyl	2·02	7·39	2·06	3·23	2·64	+ +
6-Methyl	2·00	7·37	2·05	3·22	2·63	+
7-Methyl	2·00	7·37	2·06	3·21	2·63	+
10-Methyl	1·92	7·29	2·02	3·20	2·61	+ + + +
9:10-Dimethyl	2·05	7·43	1·92	3·26	2·59	+ + +

For many of the compounds E_{CT} and T_1 are practically equal. This feature, which has been noted previously by Peticolas[13], is considered to be accidental and not of general significance, since in several of the compounds there are clear differences between E_{CT} and T_1. E_{CT} depends on the particular charge-transfer acceptor, chloranil, and quite different values of E_{CT} are obtained with benzoquinone and trinitrobenzene, although these yield similar values of I from equations analogous to (1) (ref. 12).

I is plotted against T_1 and S_1 in Fig. 1. There is a very approximate linear relationship between I and S_1, corresponding to the simple Hückel-type equation:

$$I = \alpha + bS_1 \tag{2}$$

used by some authors[20] to estimate I. The degree of scatter in the experimental data indicates the inaccuracy of this method of obtaining I. There is a similar approximate linear relationship between I and T_1, which reflects the similarity between E_{CT} and T_1 in many of the compounds.

A more significant feature is that the curves through the values of S_1 and T_1 for the polyacenes (compounds 1–4) form upper and lower limits respectively for the values of S_1 and T_1 for the other compounds. For a given I, non-linear molecular arrangements of the aromatic ring systems yield lower or equal values of S_1 and higher or equal values of T_1 than the linear polyacene arrangement. Expressed alternatively, for a given T, the S_1–T_1 separation, corresponding to the spin-reversal energy, is greatest for the polyacenes.

These considerations suggest that the mean first π-excitation energy:

$$\overline{E}_1 = \tfrac{1}{2}(T_1 + S_1) \tag{3}$$

is a more meaningful quantity to compare with I, when considering condensed-ring molecules of different shapes. I is plotted against $\overline{E}_1$ in Fig. 2. A clear linear relationship is found between I and $\overline{E}_1$ given by:

$$I = 4{\cdot}39 + 1{\cdot}15\,\overline{E}_1 \quad \text{(eV.)} \tag{4}$$

which is obeyed, within experimental error, by all except three of the compounds. Moreover, the data extrapolate to give an intercept of 4·39 eV. for graphite, the infinite condensed ring 'molecule', at $\overline{E}_1 = 0$, in agreement with the experimentally determined work function[21].

The agreement of the experimental data with (4) is sufficiently striking to consider possible causes for the discrepancies in three of the compounds. The compounds in question, tetracene, 1 : 2 : 5 : 6-dibenzanthracene and 1 : 2 : 7 : 8-dibenzanthracene, possess the longest molecules of those considered, and it is possible that the deviations are due to

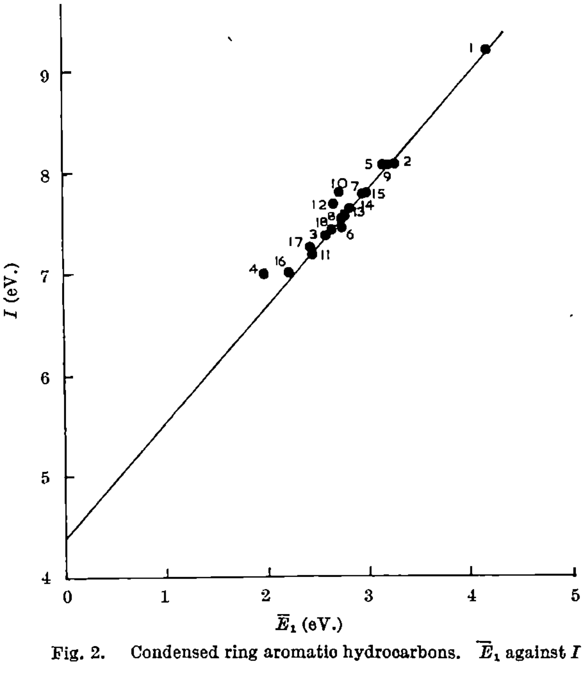

Fig. 2. Condensed ring aromatic hydrocarbons. $\overline{E}_1$ against I

the molecule being too elongated. It is of interest to note that molecular orbital theory[2] indicates that the lowest singlet state in the polyacenes changes from $^1B_{3u}{}^-$ to $^1B_{2u}{}^+$ on increasing the number of rings to 4 or more, and, while yielding reasonable values for the lower polyacenes, predicts a higher value for S_1 (3·11 eV.) for tetracene than that observed. The use of this value for S_1 would increase $\overline{E}_1$ to 2·20 eV. for tetracene and remove the anomaly. There has been some controversy over the value of T_1 for tetracene, but the experimental value taken is consistent with those of the lower polyacenes and with theory[2,14]. A further possibility is that deviations from the linear relation (1) may occur with elongated molecules.

The other two compounds have not been studied theoretically in any detail. They each have $S_1 =$ 3·14 eV. and $S_2 =$ 3·52 eV. The anomalies could be removed by using S_2 rather than S_1 in (3); but there appears little justification for this arbitrary procedure.

The measurements on the condensed-ring compounds and on the methyl derivatives of 1 : 2-benzanthracenes show that of the various energies observed only S_1 shows any degree of correlation with the carcinogenicity. This correlation has been discussed previously[22].

ELECTRICAL EFFECTS DURING DISSOLUTION AND PRECIPITATION OF ELECTROLYTES

By R. P. RASTOGI and B. P. BATRA
Chemistry Department, Punjab University, Chandigarh-3, India

AND

R. K. DASS
Physics Department, Government College, Hoshiarpur, India

EVIDENCE, although scant, has accumulated during the past three decades which indicates that potential differences are produced during phase-transformations[1-4]. Unfortunately, the phenomena associated with such transformations have not been subjected to systematic study. Hence, we have only doubtful explanations regarding the origin, build-up and the decay of potential difference. Difficulties in making reproducible measurements of potential differences are considerable. The purpose of the present article is to report the study of potential differences that are produced when the crystals of an electrolyte just appear or when these are allowed to dissolve. We will call the former the precipitation potential, and the latter the dissolution potential. So far as we are aware, this has not been reported earlier.

The initial experiments for measuring potential differences were performed in a simple way. A copper or silver tube was immersed in a bath kept at a certain temperature below the saturation temperature of the solution. This tube served as one electrode. A piece of wire of the same metal was kept in the centre of the tube, serving as another electrode. The two electrodes were connected through a Pye Scalamp galvanometer and a megohm resistance box having various steps in series. By adjusting the resistance and knowing the sensitivity of the galvanometer it could be converted into a direct-reading milli-voltmeter of high input impedance. This was considered to be sufficient for the purpose, since the saturated solutions of electrolytes are sufficiently conducting and the electrode area was quite large. The saturated solution was poured into the tube and the central electrode was immediately inserted. Potential difference was measured instantaneously. The experiments were performed with aqueous solutions of potassium chloride and potassium iodide saturated at 40° C. The asymmetry potential and thermo-e.m.f. were estimated and found to be negligible compared with the observed maximum potential differences. The decay of potential difference as a function of time was also observed. Smooth curves were obtained. The decay curves obtained by Workman and Reynolds for the freezing of ice were erratic, most probably due to difficulty in avoiding solidification on both the electrodes simultaneously. In our experiments one of the electrodes was always clean.

Difficulties in these experiments are numerous. First, the temperature corresponding to maximum potential difference is difficult to estimate, owing to the fact that nucleation may take place at any temperature intermediate between the saturation temperature and the bath temperature. Secondly, it was realized that owing to large electrode area, there was a distinctly greater possibility of nucleation occurring in crevices. This was quite clear, since great difficulty was encountered in cleaning the electrodes after each experiment so as to give negligible asymmetry potential.

These difficulties were removed to a great extent in subsequent experiments. The saturated solution was kept in a 'Pyrex' test-tube, closed at the upper end by a cork through which two electrodes, of good connecting wire, passed. One of the electrodes was in the form of a spiral. This almost touched the bottom of the tube. The other electrode just touched the surface of the solution. This was done to ensure that deposition of the crystals did not occur simultaneously on the two electrodes. If the nucleation or crystallization occurs on the two electrodes then the potential difference is neutralized or obscured. To guard against this, the second electrode was only inserted when the observations were to be made. Potential difference was measured with a vacuum tube voltmeter giving values that were correct to ± 5 mV. The 'Pyrex' tube was kept in a large beaker containing water. The outer bath was cooled in a controlled way. The cooling-rate was about 1 deg. in 5 min. The fall in temperature of the bath was followed closely by the aqueous solution of electrolytes in the 'Pyrex' tube. As soon as the first crystals appeared on the electrode, the potential difference was noted. The temperature of the bath was also noted at the same time. The crystallization at any desired temperature was induced by seeding. In this manner, the potential differences for a number of electrolytes were noted for different degrees of undercooling. To give an idea of the magnitude of the effect, only maximum values are shown in Table 1.

Table 1. PRECIPITATION AND DISSOLUTION POTENTIALS FOR ELECTROLYTES
(For precipitation potentials, the saturation temperature was 50° C.)

Substance	Precipitation potential		Dissolution potential	
	Temperature (°C.)	Potential difference (mV.)	Temperature (°C.)	Potential difference (mV.)
Potassium bromide	41	115	70	505
Potassium nitrate	44	120	80	184
Sodium acetate	42	460	70	350
Potassium acetate	47	640	70	440
Ammonium chloride	43	155	70	320
Potassium chloride	45	220	70	206
Potassium iodide	40	145	70	750
Ammonium bromide	40	350	70	450
Oxalic acid	45	450	50	196

The reverse effect involving measurement of dissolution potential was also studied in a simple way. Silver wires were used as electrodes. One of the electrodes was kept in a test-tube in which aqueous solution of the electrolyte saturated at 70° C. or 80° C. was kept. On cooling to room temperature or even lower, the electrode was covered with a thick deposit of freshly prepared crystals. The tube was broken at the bottom, so that excess of water was removed. Now, the broken tube along with the electrode was dipped in water or in the solution of the same electrolyte at a definite concentration. The other electrode was kept in water or in the solution beforehand. The two electrodes were connected to a direct-reading millivoltmeter made from a Pye Scalamp galvanometer as described earlier. As soon as the electrode embedded with crystals was dipped, an instantaneous deflexion in the galvanometer was observed. A large number of electrolytes were investigated. The effects of temperature, concentration and stirring were also investigated. The maximum values of dissolution potentials observed in water are also given in Table 1.

The following conclusions can be drawn from the data collected in the course of this work:

(1) The potential difference is developed as soon as a tiny crystal is formed at the electrode. However, we cannot say whether the potential difference is developed when the crystal nuclei is just formed or when it grows to certain dimensions. In the same manner, dissolution potential is developed as soon as the first crystals go into the solution.

(2) The electrode at which the crystallization takes place was always found to be positive. Similarly, in the case of dissolution potential, the electrode on which the dissolution took place was found to be positive.

(3) The precipitation potential increases with the degree of undercooling. The dissolution potentials also increase systematically in most cases as the temperature of the water is increased.

(4) The dissolution potential of an electrolyte in an aqueous solution of the same is a function of concentration. Its value increases as the dilution is increased.

(5) As the crystallization or dissolution proceeds, the potential difference diminishes. The decay curve of potential difference would be erratic when the crystals are deposited simultaneously on the two electrodes or when the dissolution takes place from both electrodes.

(6) Both phenomena are independent of the nature of the electrodes.

The exact mechanism of these phenomena is difficult to establish at present until more information is available. It seems reasonable to assume that an electrical double-layer is formed when the solid phase is just formed or a fresh double-layer is regenerated when the solid just dissolves. The concept of electrical double-layer may be useful here, since it is able to explain adequately a number of interfacial phenomena[5]. But, if so, the electrical potential difference should be developed at the appearance of first crystal nucleus. It is difficult to provide evidence for it.

The results show clearly that the greater the rate of transformation, the greater is the potential difference developed. B. Gross[6] has developed a theory of such phenomena which relates the potential differences to the rate of transformations. According to his model, as the interface advances, it leaves behind a trail of space-charge in the solid between the region deep in the solid and the liquid, which builds up a potential difference. However, it is difficult to imagine how these charges are dissipated since ultimately the solid must be electrically neutral. Moreover, in the present case the electrical conductivity of solid electrolyte and the diffusion of the electrolyte in the solution would be important factors which are not taken into account by this theory.

More detailed investigations are in progress and may be published in due course. This work forms part of a project sponsored by the Indian Council of Scientific and Industrial Research.

METAL CHLORIN COMPLEXES IN RECENT SEDIMENTS AS INITIAL PRECURSORS TO PETROLEUM PORPHYRIN PIGMENTS

By G. W. HODGSON and ERIC PEAKE

Research Council of Alberta, Edmonton, Canada

THE presence of the isocyclic ring in the porphyrins found in crude oil is usually regarded as indicative of a chlorophyll origin for the petroleum porphyrin–metal complexes[1]. Since it appears, therefore, that pigments derived from chlorophyll probably accompany the general organic matter in its conversion to crude oil, it is of interest to establish the path by which chlorophyll becomes transformed to petroleum porphyrin pigments. In this manner it may be possible to define the chemical environments of the formation of crude oil more clearly.

Chlorophyll is readily converted to phæophytin by the loss of magnesium[2]. However, the path by which phæophytin is converted to metal–porphyrin complexes is not well defined; as discussed in an earlier communication[3], it may involve one of two major intermediates. In one, the phæophytin forms a metal–phæophytin complex, a chlorin complex, which is afterwards reduced and dehydrogenated to a metal-containing porphyrin. In the other, the phæophytin is reduced and dehydrogenated to a free porphyrin which afterwards forms a complex with a metal. Heretofore, however, neither chlorin complexes nor free porphyrins have been reported in recent sediments.

Recently, however, a porphyrin–metal complex has been found in post-glacial lake sediments, having light-absorption maxima at 410, 536 and 575 mμ (ref. 3). There is evidence that it is a carboxylated porphyrin complex, only one step removed from the decarboxylated porphyrin–metal complexes of crude oil.

The purpose of this article is to report the results of attempts to close the gap between the free chlorins, which are abundant in potential petroleum source sediments, and the porphyrin–metal complex, which exists in sediments geologically very little older. Present chemical work in this laboratory shows the likely initial steps, and these are confirmed by new pigment discoveries in recent lake and delta sediments.

From considerations of the reactivity of the peripheral groups on the chlorophyll molecule, it appears reasonable to believe that the main reaction path would include phæophytin, phæophorbide, phæoporphyrin, phylloerythrin, and deoxophylloerythrin, leading to deoxophylloerythroetioporphyrin of crude oil. A series of experiments subjecting phæophorbide to extended thermal action in a methanol–water system at 180° C. appeared to confirm such a sequence in principle. Compounds essentially similar to phæoporphyrin and phylloerythrin occurred within a few hours, followed shortly by two deoxophylloerythrin-like substances. Identification of the compounds was based on acid-solubility characteristics in addition to spectral configurations which have been established in this laboratory for the known compounds prepared according to Fischer[4]. Thus, the evolution of such compounds in a relatively simple thermal system indicates that such a pathway may be possible in this particular metal-free environment.

However, free porphyrins in potential petroleum source sediments have not been reported, and present work in this laboratory has as yet failed to reveal any. Such negative findings, therefore, tend to direct attention to the other path, namely, that involving the formation of a metal–chlorin complex which is afterwards transformed to a metal–porphyrin complex.

To investigate this point, various chlorophyll-containing mixtures of either spinach leaves or commercial chlorophyll were allowed to react with various vanadium salts in the presence of sodium sulphide in aqueous systems at temperatures ranging from 90° to 150° C. In most cases, starches, sugars and proteins were included as well, further to simulate source sediment environments. Vanadium complexes of various pigments appeared in the reaction systems after several hours, with the major pigment classes characterized by absorption spectra maxima at about 650 and 620 mμ for one, and 650 and 590 mμ for another. The first appeared to be a precursor of the second. A further reaction of phæophytin *a* with ammonium metavanadate in the presence of only sodium sulphide and an unsaturated vegetable oil in an aqueous system at 105° C. produced the same two classes of compounds in substantial yields in 60–70 hr. Part of each class of compounds showed the presence of free carboxyl groups, indicating at least partial hydrolysis of the phytyl alcohol group from the phæophytin. These compounds were insoluble in 6 *N* and 12 *N* hydrochloric acid and were, therefore, regarded as metal complexes of the pigments, presumably vanadium complexes. The location of spectral peaks indicated complexes of chlorins rather than porphyrins, since the latter absorb in a significantly lower spectral range[5].

Similar chlorin pigments were evident in recent sediments obtained from widely differing environments. For example, sediments from Lake Wabamun, a large, relatively shallow lake about 40 miles west of Edmonton, Alberta, Canada, were exhaustively extracted with aqueous acetone and the extracts transferred to ether. Uncomplexed chlorin pigments, principally phæophytin *a* and phæophorbide *a*, were acid-extracted from the ether, leaving an appreciable amount of chlorin-like material along with carotenoids and other substances. The acid-insoluble material, which would include any metal complexes of chlorins or porphyrins present in the sediments, was transferred to *n*-hexane and chromatographed on cellulose fibre.

Good spectral evidence was obtained for three pigments which were apparently metal complexes as indicated by both their acid-insolubility and spectral characteristics. Absorption maxima for the three compounds were: (*a*) 403, 598 and 648 mμ; (*b*) 413, 589 and 628 mμ; (*c*) 411 and 648 mμ.

The general spectral appearances were those of metal chlorins, similar to those of the products obtained in the vanadium–phæophorbide reactions reported above, and to that of the nickel phæophytin reaction previously reported at 410 and 635 mμ (ref. 6).

Analyses for vanadium, nickel and copper showed positive results for both vanadium and nickel. Material balances were difficult to test because of the lack of precise knowledge of the extinction coefficients of the pigments, and the incomplete separation of organic matter which was characterized by strong absorption below 500 mμ. Nevertheless, using the known extinction coefficient for the nickel complex of phæophytin[6], it was possible to show the presence of enough of both vanadium and nickel to account for the apparent amount of chlorin present. Thus, it is clear that recent sediments contain not only free chlorins but also metal-complexed chlorins. Accordingly, it is reasonable to suggest that the overall reaction path for the formation of petroleum porphyrin–metal complexes involves the entry of the metal into the pigment at a very early stage, the chlorin stage, in the general development of the pigment.

It is of some significance to note that the occurrence of metal–chlorins appears to be quite widespread. Metal–chlorin compounds very similar to those of Lake Wabamun, a plains lake, were found in a deep mountain lake, Pyramid Lake, in Jasper National Park, in the sediments of the delta of the Mackenzie River in the Canadian Arctic, and in the sediments of Laguna Madre in the Gulf of Mexico.

A further observation in the Lake Wabamun sediments is worthy of considerable attention. The sediments on the surface of the lake bottom contained not only metal complexes of chlorins but also, in addition, a metal complex of a porphyrin. It occurred in much smaller concentrations than the chlorin complexes, and had absorption maxima at 410, 530 and 570 mμ. Alkali solubility indicated the presence of a free carboxyl group. Another slightly different porphyrin complex had been found in a nearby lake as previously reported[3], but the significant difference is that in the present case the sediments were surface sediments, very recently deposited, in contrast with the deeper sediments which were probably several thousand years old.

In summary, there is much evidence to indicate that the reaction path for the formation of petroleum metal–porphyrin pigments involves the introduction of the metal into the pigment at a very early stage of development, the chlorin stage, and that almost the entire process is completed in a very short period of time; only hundreds of years are required for the deposition of a few inches of lake sediments.

We are pleased to acknowledge the assistance of R. H. Harvey and other skin-divers of the Edmonton Aquanauts for obtaining the lake-bottom sediments, G. H. Johnston, of the National Research Council, for the delta samples, Gene Rusnak, at present of the Marine Laboratory, University of Miami, for the sediments of Laguna Madre, and B. L. Baker, R. M. Elofson, and Brian Hitchon for general assistance and guidance.

HISTOCHEMICAL DEMONSTRATION OF GAMMA-GLUTAMYL TRANSPEPTIDASE

By Prof. Z. ALBERT, Dr. MARIAN ORLOWSKI and Dr. A. SZEWCZUK

Polish Academy of Science, Department of Experimental Oncology and Department of Biochemistry, Institute of Immunology and Experimental Therapy and Third Medical Clinic, School of Medicine, Wroclaw, Poland

IN a previous paper two of us[1] described the occurrence of a specific peptidase in blood serum and some tissues. The enzyme hydrolysed some α-(N-γ-DL-glutamyl)-aminonitriles and was suspected to be a γ-glutamyl transpeptidase, similar to that described by Hanes *et al.*[2]. Further work confirmed this supposition and recently[3] a new method was described for the determination of γ-glutamyl transpeptidase, using γ-L-glutamyl-α-naphthylamide as substrate. The enzyme catalyses with this substrate a transpeptidation reaction according to the following scheme:

2γ-L-glutamyl-α-naphthylamide → α-naphthylamine + γ-L-glutamyl-γ-L-glutamyl-α-naphthylamide

The amount of α-naphthylamine liberated during the enzymic reaction was estimated by a modification of the Bratton and Marshall procedure[4] and used as a measure of enzyme activity. With this method, the enzyme activity was found to be very high in human kidney. Much lower activities were found in human liver, spleen and pancreas. Some activity was found in human serum and urine[3].

This article deals with the histochemical demonstration of γ-glutamyl transpeptidase in tissue sections of some animals and human beings. γ-L-glutamyl-α-naphthylamide was used as substrate and the liberated α-naphthylamine was coupled to an azo-dye with the aid of fast garnet *GBC* salt. The composition of the incubation mixture was as follows: 6 ml. substrate solution (5·44 mgm. γ-L-glutamyl-α-naphthylamide dissolved in 0·9 per cent sodium chloride), 4 ml. buffer solution (0·1 *M* phosphate buffer *p*H 6·7, or 0·2 *M* citrate–phosphate buffer at the same *p*H), 5 mgm. of fast garnet *GBC* salt per 10 ml. of incubation mixture. This incubation mixture was prepared fresh daily. Good results were also obtained using γ-L-glutamyl-β-naphthylamide. However, the solubility of this compound is very low at *p*H 6·7, and even 0·2 mgm. of this substrate per ml. of incubation mixture was difficult to dissolve. The hexazonium salt of pararosanilin[5] was also used as coupling agent instead of fast garnet *GBC*. Places with γ-glutamyl transpeptidase activity exhibit a brown-reddish colour with fast garnet *GBC* or a yellow colour with the hexazonium salt of pararosanilin as coupling agent.

The optimum *p*H for γ-glutamyl transpeptidase is about 8·8 and at *p*H 6·7 the enzyme activity amounts only to a few per cent of that measured in optimal conditions. Acceleration of the enzymatic reaction could be obtained at *p*H 6·7 by the addition of glycylglycine, which serves as an acceptor of the γ-glutamyl moiety according to the following reaction[3]:

$$\gamma\text{-L-glutamyl-}\alpha\text{-naphthylamide} + \text{glycylglycine} \xrightarrow{\text{enzyme}}$$
$$\rightarrow \gamma\text{-L-glutamyl-glycylglycine} + \alpha\text{-naphthylamine}$$

For acceleration of the histochemical reaction, we have added 20 μmoles of glycylglycine per ml. of incubation mixture. The addition of glycylglycine is particularly recommended for the demonstration of γ-glutamyl transpeptidase in tissues with low enzyme activity.

Healthy mice, rats, guinea pigs and rabbits were used for our experiments. Moreover, kidney sections were taken from human subjects some hours after death in street accidents. Sections, 3–4 mm. thick, were prepared from kidneys, spleen, liver, pancreas, testes, myocardium and lungs, and fixed in acetone, absolute ethyl alcohol or 6 per cent neutralized formalin. The fixation time was 11 hr. at 4° C. As freezing with carbon dioxide gave inferior results, the sections were embedded in paraffin. 5–10μ thick sections were incubated in the given mixture for varying periods of time. 5–20 min. were sufficient for kidney while for other tissues an incubation time of 1–3 hr. was necessary. Following incubation, the slides were immersed for 2 min. in 0·1 *M* solution of copper sulphate and then stained with hæmatoxylin for 1–2 min. Afterwards, they were rinsed with 0·9 per cent sodium chloride and mounted in glycerol-gelatin.

The following localization of the enzyme was observed. In the kidney, the lumen of the loop of Henle and to a less extent of the proximal convolutions of the tubulus shows homogeneous masses with a strong positive reaction. The enzyme was not visible in the glomeruli and collecting tubules. In mouse and rat kidneys the enzyme is distributed quite regularly all over the cortex (Fig. 1) whereas in guinea pigs and rabbits γ-glutamyl transpeptidase is located almost exclusively in medullary rays (Fig. 2). The localization of the enzyme in normal men is similar to that found in rabbits and guinea pigs. It is to be stressed that the homogeneous masses with a strong positive reaction adhere to the surface of epithelial cells not only in proximal convolutions of the tubulus, which possess a distinct brush border, but also in the loop of Henle devoid of this brush border.

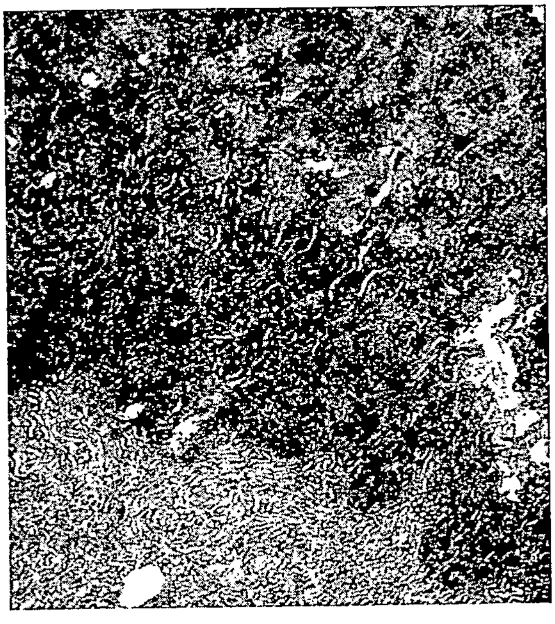

Fig. 1. γ-glutamyl transpeptidase in the cortex of the mouse kidney. (× 42)

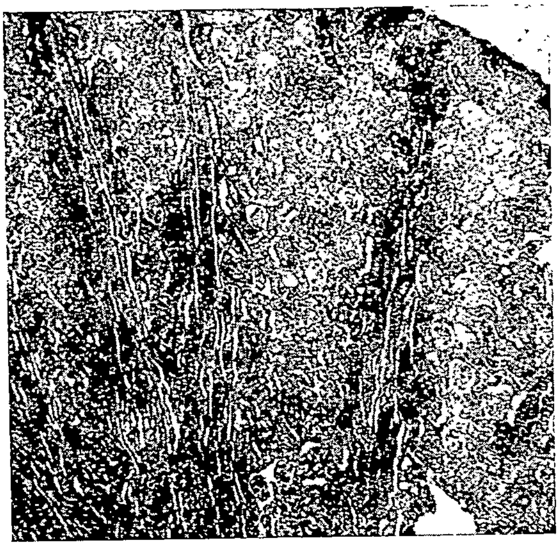

Fig. 2. The localization of γ-glutamyl transpeptidase in medullary rays in the kidney of the guinea pig. (× 42)

With the spleen, the enzyme is visible in guinea pigs, rabbits and rats in the walls of some capillaries of the red and white pulp, and moreover as granules in some cells of the reticulo-endothelial system.

With the liver, a positive reaction was seen in rats in the walls of bile canaliculi and in single cells of the reticulo-endothelial system in Glisson's capsule. In rabbits the enzyme was found in the form of granules in the cytoplasm of liver cells mostly around the nucleus. It was more abundant in the periphery than in the centre of lobules. The greatest enzyme activity was found in guinea pigs, taking the shape of confluent tiny granules on the periphery of liver cells and, as in rabbits, more profuse in the peripheral than the central part of the lobules.

With the pancreas, a relative abundance of the enzyme was seen in the cells of the outer secretory system in the mouse, rat, rabbit and guinea pig. The enzyme was not found in Langerhans's islands.

With testes, a positive reaction was observed in the testes of guinea pig within spermatozoa and spermatocytes. No activity was seen in the testes of the rat and the mouse. The myocardium and lungs of the mouse, rat and guinea pig did not exhibit enzyme activity.

REACTIONS OF HÆMOPROTEINS WITH HYDROGEN PEROXIDE AND THE SUPPOSED FORMATION OF HYDROGEN PEROXIDE DURING THE AUTOXIDATION OF HÆMOGLOBIN

By Prof. D. KEILIN, F.R.S.
Molteno Institute, University of Cambridge

IT is well known that many substances undergoing autoxidation, or oxidation catalysed by metals, or by some specific enzmyes, reduce molecular oxygen, directly or indirectly, to hydrogen peroxide, which can usually be detected by some simple reagents. However, the main limitations of these reagents are that they can seldom be used for the study of the continuous formation of hydrogen peroxide and that they may interfere with the primary oxidation reactions which generate the peroxide, especially if these reactions are brought about by some unstable catalytic systems. In such cases peroxidase, catalase and methæmoglobin can be used both for the detection of hydrogen peroxide and for following its gradual generation even by very unstable biological systems. These three hæmoproteins show striking resemblances in their structure and properties, including some of their reactions with hydrogen peroxide[1–4].

Reactions of Hæmoproteins with Hydrogen Peroxide

The following few examples illustrate the reactions of hæmoproteins with hydrogen peroxide generated by an oxidation system.

(1) *Catalatic decomposition of hydrogen peroxide.* The reduction of molecular oxygen to hydrogen peroxide by glucose oxidase (notatin), which catalyses the oxidation of glucose to gluconic acid, can easily be followed manometrically[5]. Thus, catalase added to this system, by liberating oxygen from the peroxide, halves the original uptake of oxygen and brings it down to the theoretical value corresponding to the reduction of oxygen to water. Similar results have been obtained with many other oxidizing systems.

(2) *Peroxidatic utilization of hydrogen peroxide.* Of special interest in this respect was the discovery that catalase, in addition to its well-known property of decomposing hydrogen peroxide to oxygen and water, is also capable of utilizing the hydrogen peroxide generated for the peroxidatic oxidation of alcohol to aldehyde[4,5]. The concept of the peroxidatic activity of catalase was later extended to some other hydrogen donors, including hydrogen peroxide itself[6–8]. A large variety of hydrogen donors were found to undergo peroxidatic or coupled oxidation catalysed by peroxidase, catalase and methæmoglobin. These hæmoproteins, however, show marked differences in their specificity and in their catalytic efficiency towards hydrogen donors[5]. As some of these donors, like benzidine, give highly coloured products on peroxidatic oxidation catalysed by peroxidase and methæmoglobin, the presence of hydrogen peroxide can easily be detected by this well-known colour reaction.

(3) *Compounds of hæmoproteins with hydrogen peroxide.* As these hæmoproteins form with hydrogen peroxide compounds which are easily recognized by their colour and absorption spectra, they can be used for the detection of hydrogen peroxide, as reagents acting in the absence of hydrogen donors. While peroxidase and methæmoglobin can be used for this purpose in their free state, catalase gives the best result when it is used as the azide-catalase complex which, when added to a solution containing hydrogen peroxide, changes its colour and the pattern of its absorption spectrum[1,3]. Moreover, azide catalase enables one to follow the formation of hydrogen peroxide even during the oxidation of sodium dithionite ($Na_2S_2O_4$) when other reagents cannot be used.

Is Hydrogen Peroxide formed during the Autoxidation of Hæmoglobin?

Oxyhæmoglobin, like hæmoglobin, is a compound with divalent iron atoms which may undergo slow autoxidation to the tervalent iron atoms of methæmoglobin. It was shown that up to 2 per cent of endoerythrocytic mammalian hæmoglobin *in vivo* may be present as methæmoglobin[9]. The hæmoglobin of *Gasterophilus* larvæ[10] and of certain parasitic nematodes[11], as well as myoglobin, are much more susceptible to autoxidation, especially during their purification, than are the mammalian blood hæmoglobins.

Of great interest, however, is the fact that while the oxidation of oxyhæmoglobin to methæmoglobin by potassium ferricyanide liberates all the bound oxygen, that is, 1 mole oxygen per gram-atom of iron, the autoxidation of oxyhæmoglobin liberates less than 50 per cent of the bound oxygen, instead of 75 per cent had some oxygen been used only for the oxidation of the divalent iron atoms of hæmoglobin. Brooks[12], who was the first to study the kinetics of the autoxidation of hæmoglobin, showed that the rate of this reaction at different oxygen pressures is proportional to the concentration of deoxygenated hæmoglobin. The observed first-order rate constant for the autoxidation of hæmoglobin is a function of the oxygen pressure, and has a well-defined maximum at about 20 mm. The kinetics and the possible mechanism of this reaction have recently been studied by several workers, both for hæmoglobin and myoglobin. The autoxidation is greatly accelerated by lowering the *p*H to about 5 and raising the temperature to 39°. Denaturation of oxyhæmoglobin by acid or alkali, which brings about the immediate oxidation of hæms to acid and alkaline hæmatin respectively, is also accompanied by the liberation of only a certain fraction of the bound oxygen.

It was suggested[13] that a part of the bound oxygen, which is not liberated from oxyhæmoglobin during its autoxidation, is activated and reacts with globin to form hydrogen peroxide which can be used by hæmatin for the catalysis of the peroxidatic oxidation of substances like ascorbate, bilirubin and biliverdin.

Unfortunately, no proper control experiments have been carried out on the oxidation of these substances by a solution of a parahæmatin or hæmochromogen in the absence of peroxide. The autoxidation of myoglobin was found to be accompanied by an uptake of 2·5 moles oxygen for each mole of metmyoglobin formed[14]. It is now generally accepted that the autoxidation of hæmoglobin and myoglobin to methæmoglobin and metmyoglobin respectively, brings about the simultaneous oxidation of some hydrogen-donor groups on globin itself. Although the mechanism of these autoxidation reactions is not yet properly understood, several workers[13–15] postulated the important part played in these reactions by hydrogen peroxide and related free radicals.

One of the objects of the present work was to find whether the postulated formation of hydrogen peroxide during the oxidation of oxyhæmoglobin on mild acidification can be demonstrated by some of the reactions of hydrogen peroxide with hæmoproteins which were discussed in the first part of this communication.

For this purpose experiments were carried out on horse-blood oxyhæmoglobin purified by crystallization which was repeated three times; the oxidation of oxyhæmoglobin was followed spectroscopically and the liberation of oxygen was determined manometrically.

The main results of these experiments can be summarized as follows:

(1) Contrary to claims made by previous workers[15], the addition of catalase to oxyhæmoglobin, prior to mild acidification, made no difference either to the rate of its oxidation to methæmoglobin, or to the amount of bound oxygen liberated from oxyhæmoglobin; ethanol added to this system failed to undergo oxidation to aldehyde.

(2) Benzidine added to the solution of oxyhæmoglobin did not undergo oxidation to a dark blue product on mild or strong acidification of this solution. The reaction failed even when a strong solution of purified peroxidase was mixed with oxyhæmoglobin. Yet, on the addition of traces of hydrogen peroxide to this solution, benzidine was rapidly oxidized to a dark blue product.

(3) Methæmoglobin formed during mild acidification never showed the presence of hydrogen peroxide by the formation of the methæmoglobin–peroxide compound, which could easily have been recognized by its red colour and the pattern of its absorption spectrum. The same applied to peroxidase added in a suitable concentration to an oxyhæmoglobin solution prior to its acidification.

(4) About 0·5 ml. of solution of pure peroxidase (0·37 × 10^{-3} *M*) enclosed within a small dialysing sac, and showing its characteristic absorption spectrum, was immersed in 20 ml. of solution of oxyhæmoglobin (1·4 × 10^{-3} *M* hæmin) which was acidified while being vigorously stirred. The dialysing sac, removed at different intervals of time for spectroscopic examination, failed to reveal any change in the absorption spectrum of peroxidase. Similar results were obtained when the dialysing sac contained a strong solution of azide catalase (in the presence of a large excess of azide) which is one of the most sensitive reagents for hydrogen peroxide.

All these experiments failed to give any indication of the formation of hydrogen peroxide in a solution of acidified oxyhæmoglobin undergoing autoxidation to methæmoglobin or to acid hæmatin. The problem of the mechanism of autoxidation of hæmoglobin and myoglobin therefore still remains open for further investigation.

RISE OF ANTIBODY TITRE IN CELL-FREE SPLEEN PREPARATIONS INCUBATED *IN VITRO*

By DR. DIETER H. SUSSDORF
Division of Chemistry and Chemical Engineering, California Institute of Technology, Pasadena

AN initial attempt to demonstrate antibody-forming activity by cell-free tissue preparations was made by Šterzl and Hrubešová[1]. They injected cell-fractions and nucleoproteins from spleens of rabbits immunized with *Salmonella paratyphi B* vaccine into unimmunized neonatal rabbits and observed the appearance of specific agglutinins in the recipients. However, it is still not clear whether the antibodies appearing in the recipient animals were synthesized *de novo* after transfer or were initially bound to and afterwards released by the transferred materials[2]. With respect to the second possibility, a report by Feldman *et al.*[3] is of interest. They found that ribonucleoprotein-bound antibody was immunologically inactive but could be titrated following enzymatic degradation of the ribonucleoprotein.

The aim of the present work was to follow in an *in vitro* system the hæmolysin titres of extracts prepared from spleens of immunized rabbits. The animals were injected intravenously with standard doses of 0·8 × 10^9 washed sheep erythrocytes/kgm. (equivalent to 1 ml. of a 5 per cent suspension/kgm.). Primary stimulation consisted of a single injection on days 0, 1 and 3, and secondary stimulation of a single dose given 8 weeks after primary injection.

The preparation of an experimental extract (series *A*) was as follows: five rabbits were killed by an intravenous injection of air on day 4 or 5 following the first primary, or on day 3 following the secondary, injection. On these days, the serum hæmolysin titres of the animals ranged between 450 and 3,200 hæmolytic units/ml. The spleens of the rabbits were removed (average combined weight 9·4 gm.), cut into small pieces, and rinsed with about 5 ml. medium. The latter was a defined, complete tissue culture medium[4] with an amino-acid composition corresponding to that of rabbit γ-globulin[5]. For the purpose of these experiments, 0·7 μmole adenosine triphosphate[6] was added to the medium. The rinsed spleen pieces were combined with 1·0 ml. medium/gm. tissue and homogenized by 10 down–up excursions in a Potter–Elvehjem tissue grinder with a 'Kel-F' pestle. All procedures were carried out at 3° C. Probably not more than 75 per cent of the spleen cells were extracted by this method. This estimate is based on a count of the free nuclei present in the homogenate prior to centrifugation and the comparison of this number with the estimated number of cells representing 1 gm. of spleen tissue.

The homogenate was centrifuged at 500*g* for 10 min., and the resulting supernatant re-centrifuged at 1,700*g* for 15 min. The second supernatant (average volume 6·4 ml.), containing the large and small granule, and the soluble cell fractions, was transferred into a small Petri dish which was placed in a tissue culture incubator (37° C., 85 per cent humidity, 5 per cent carbon dioxide, 95 per cent air). The total time elapsed between homogenization and the beginning of incubation was 70–80 min. To avoid clotting, the extract was gently agitated with a magnetic stirrer during the second hour of incubation. Samples of 0·1 ml. were removed with ultramicro-pipettes at 0, 0·5, 1, 2, 3, 4, 6, 8, 12, 15 and 18 hr. Since it was found earlier that the samples did not contain detectable amounts of complement, complement inactivation was omitted.

The samples were diluted 1 : 50 with veronal buffer and cleared at 1,700*g* for 20 min. Their hæmolysin titres, determined according to the method of W. H. and L. G. Taliaferro[7,8], were expressed in photometrically determined 50 per cent hæmolytic units/ml. extract. A 50 per cent unit is defined as the reciprocal of the amount of extract lysing 50 per cent of 3·2 × 10^8 sheep erythrocytes in the presence of four 50 per cent units of complement. The over-all error of this titration method did not exceed 5 per cent.

Two types of controls were employed. The first (series *B*) involved the preparation of extracts from normal spleens to which hæmolytic serum was added immediately before homogenization. The amount of antibody added approximated the zero-time hæmolysin-level of the experimental extracts. The purpose of these controls was to determine the immunological stability of hæmolysins during *in vitro* incubation. The second set of controls (series *C*) was prepared from normal spleens alone.

Of nine experimental extracts, seven showed a significant elevation of hæmolytic activity, the net increase ranging between 21 and 99 hæmolytic units/gm. spleen. Because of 8-hr. intervals between samplings, one run could not be used for statistical evaluation, and only six of the positive experimental extracts are listed in Table 1 (*A*). Preparations from rabbits stimulated with primary or secondary antigen injections (four and two extracts, respectively) were considered together. The total incubation time was 8 hr. for four and 18 hr. for two of the series *A* extracts. Table 1 also lists the results obtained with five extracts from series *B* controls, three of which were incubated for 8 hr., and two for 18 hr. Not shown in Table 1 are three extracts of series *C* (normal spleens alone), since no hæmolytic activity could be detected during the 8-hr. incubation period.

Table 1. HÆMOLYTIC ACTIVITY DURING *in vitro* INCUBATION OF CELL-FREE SPLEEN PREPARATIONS

	A Experimental extracts (spleens of immunized rabbits)	*B* Control extracts (spleens of normal rabbits; immune serum added)
No. of extracts*	6	5
Combined spleen weight (gm.)	9·4 ± 0·4	7·0 ± 0·1
Volume of extract (ml.)	6·4 ± 0·7	5·5 ± 0·4
Hr. at beginning of titre rise above zero-time level	1·3 ± 0·4	(1·7 ± 0·9)†
Hr. of maximum titre (*A*) or of beginning of titre plateau (*B*)	7·3 ± 0·9	2·4 ± 0·2
Zero-time titre‡	128 ± 26	143 ± 34
Maximum titre‡	176 ± 32	148 ± 34
Net titre increase‡	48 ± 11	5 ± 5

Values given are means ± standard errors

* Each extract was prepared from the pooled spleens of five rabbits.

† The titres of only three of these extracts rose above zero-time level.

‡ In 50 per cent hæmolytic units/gm. spleen.

Mean titration curves for series *A* and *B*, covering 8 hr. of incubation, are shown in Figs. 1 and 2. The graphs were obtained by calculating the mean hourly titres for a given series from the hæmolysin curves of the individual extracts, and plotting these means against time. Differences between certain parameters listed in Table 1 and corresponding ones of the

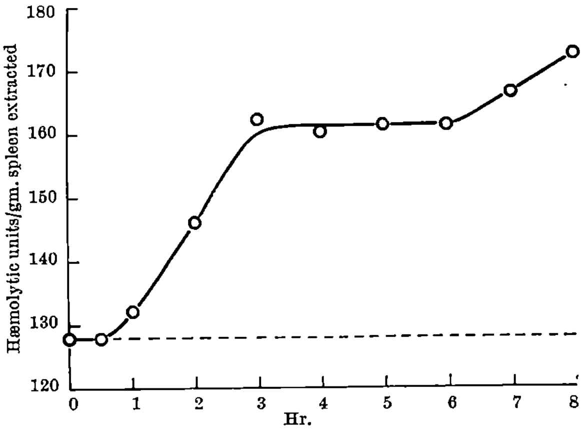

Fig. 1. Experimental extracts (series *A*). Mean hæmolysin curve of six *in vitro* incubated spleen extracts from rabbits immunized with sheep erythrocytes. (Each extract was prepared from five pooled spleens)

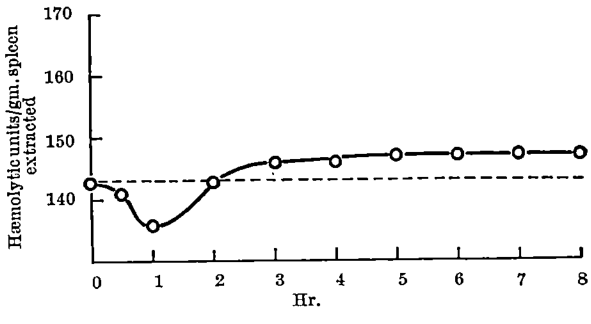

Fig. 2. Control extracts (series *B*). Mean hæmolysin curve of five *in vitro* incubated extracts from normal rabbit spleens to which hæmolytic serum was added before homogenization. (Each extract was prepared from five pooled spleens)

average curves are due to differences in the statistical approaches used to calculate the two sets of data.

The configuration of the mean hæmolysin curve for series *B* indicates a temporary immunological inactivation and subsequent reactivation of about 5 per cent of the added antibody. Inactivation may have been due to the adsorption of globulins to sub-cellular particles such as mitochondria and microsomes. The hæmolysins probably became detectable again after dissociation from these particles. Since adsorption may have begun during homogenization (70–80 min. prior to incubation), the initial titre of these extracts probably was at the level of the final titre plateau.

The two-step antibody rise shown by the mean hæmolysin curve for series *A* was displayed by five of the six extracts in this series. In some preparations, the initial antibody increase was followed by a shallow decline lasting 2 hr. or less. In the two extracts incubated for 18 hr., the second hæmolysin rise led to a plateau beginning at about 8 hr. which remained constant during the remainder of the incubation period.

The progressive increase in titre observed over a period of 8 hr. in spleen extracts from immunized animals suggests either the release of preformed antibody alone from a sub-cellular component, or the release of both preformed and newly synthesized antibody. The successive occurrence of these two processes may be indicated by the biphasic character of the mean hæmolysin curve.

I am indebted to Prof. Dan H. Campbell for his advice, and for supplying technical assistance and facilities.

This work was supported by fellowship *EF*-9543 from the National Institute of Allergy and Infectious Diseases, U.S. Public Health Service.

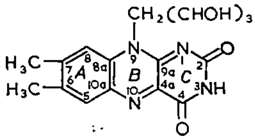
BIOSYNTHESIS OF RIBOFLAVIN IN CELL-FREE SYSTEMS

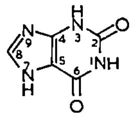
By Prof. T. W. GOODWIN and Dr. A. A. HORTON*

Department of Agricultural Biochemistry, University College of Wales, Aberystwyth

It has now been well established that ring *C* and N-9 and N-10 of ring *B* of riboflavin (I) are formed from a purine (II) derivative following the loss of C-8 of the purine[1,2]. For example, Plaut[3] and his colleagues observed that the labelling pattern in riboflavin synthesized by the mould *Ashbya gossypii* fed carbon-14-HCO'_3, -H.COO′ and -glycine was identical with that observed in purines synthesized in the presence of the same labelled substrates, and similar results have been obtained using carbon-14-L-serine[4] and carbon-14-L-threonine[5]. Experiments with generally labelled carbon-14 adenine showed that incorporation did not first involve the degradation of a purine and then re-synthesis of the metabolites into riboflavin[6], and these results have been confirmed using [^{14}C : ^{15}N] xanthine and guanine[7].



(I)

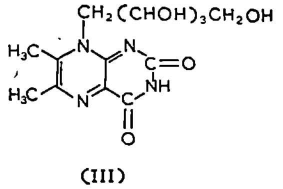


(II)

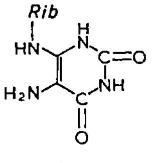
Under suitable cultural conditions up to 70 per cent of added carbon-14 guanine is incorporated into riboflavin by the yeast *Candida flareri*[8]. C-8 of the purine is lost during incorporation, which would indicate that 4,5-diaminouracil, or more likely a derivative, is the intermediate[9]. Support for this view came when 4,5-diaminouracil was identified as a metabolite of the flavinogenic fungus *Eremothecium ashbyii*, but the methods employed in these experiments would not preclude its existence *in vivo* as a ribose phosphate or ribitol derivative[10]. This raises a central problem in elucidating the mechanism of biosynthesis. At what stage and how does the ribitol side-chain become attached to N-9? The problem has not yet been settled; all that can be said at the moment is that as 6-7-dimethyl-8-ribityllumazine (III) is a precursor of riboflavin (see below), the ribitol residue appears before the completion of ring *A*. The only hint of mechanism comes from the work of Forrest and McNutt[11] with generally labelled carbon-14 guanosine; they found that the riboflavin arising from this substrate was much more strongly labelled in the ring system than in the ribitol side-chain; this observation strongly suggests that the ribitol did not arise by reduction of the ribose residue. However, this cannot be accepted out of hand, because guanosine could be in equilibrium with guanine and ribose-1-phosphate (reaction 1) in the presence of a nucleoside phosphorylase, and if the pool size of ribose-1-phosphate were much larger than that of guanine (and this is highly probable because it is 'active glycine', and thus purine, which is the limiting factor in flavinogenesis in *E. ashbyii*), then this would lead to the observed results:

$$\text{guanosine} + Pi \rightleftharpoons \text{guanine} + \text{ribose-1-phosphate} \quad (1)$$

On the assumption that 4-ribitylamino-5-amino-uracil (IV) might be the active precursor of riboflavin, a number of investigators synthesized this compound, which was found to be very unstable. Katagiri *et al.*[12]



(III)



(IV)

(2)

have reported a slight conversion of this compound into riboflavin in *Aerobacter aerogenes*, but Plaut, who has given a full chemical synthesis of the compound[13], has not yet reported on its biological activity and has indicated, in a personal communication, that his results were most inconclusive; Kishi *et al.*[14] also failed to demonstrate any significant production of riboflavin when they used a crude enzyme preparation of *Eremothecium ashbyii*. With the collaboration of Dr. B. G. Audley, we synthesized (IV), using essentially Plaut's methods, and consistently failed to observe its conversion by cell-free extracts of *Candida flareri* into either 6,7-dimethyl-8-ribityllumazine or into riboflavin, although many variations in preparing the extracts and in incubation conditions have been tried[15]. If (IV) were a precursor of riboflavin, then the experimental conditions necessary for the demonstration of precursor activity are extremely elusive.

However, investigations on the final stages of riboflavin biosynthesis have met with a little more success. Masuda in 1956 isolated and identified 6,7-dimethyl-8-ribityllumazine (III) from the mycelium of *E. ashbyii*[16]. He finally proved the structure by total synthesis[17]. Thanks to the generosity of Dr. Masuda, who kindly provided us with a crystalline specimen of (III), we were able to demonstrate that cell-free extracts (produced by sonic disintegration), but not intact cell suspensions, of *Candida flareri* rapidly converted it into riboflavin. The activity resided in the supernatant fraction (not sedimentable at 100,000*g*) of the extract and the maximum conversion obtained under many varying conditions was always approximately 30 per cent. It is interesting to record here that, with Dr. B. G. Audley, we found that distilled water (*p*H 6·0) was an excellent solvent for separating (III) from riboflavin on paper chromatograms. The presence or absence of possible sources of the 4-carbon unit (for example, pyruvate, acetate, acetoin) required for the completion of ring *A* had little effect on the conversion, and riboflavin was synthesized from (III) alone in extracts which had been dialysed for 18 hr. against running de-ionized water (20 litres). The extent of conversion in such dialysed extracts was also unaffected by addition of possible 4-carbon precursors, by 10^{-3} *M* fluoride, or by the addition of a mixture of ATP, coenzyme *A*, thioctic acid, thiamine, diphosphopyridine nucleotide, and magnesium and calcium ions. While this work was in progress, similar results were reported for extracts of other organisms, including *E. ashbyii*[12,18], *Ashbya gossypii*[18,19], *Escherichia coli*[12], *Neurospora crassa*[12], *Lactobacillus plantarum*[12], bovine liver[12] and *Mycobact.* spp.[18]. Also in agreement with our results, it was found that intact cells of *E. ashbyii*[18,20] and *A. gossypii*[19] failed to carry out the conversion; furthermore, extracts of a riboflavin-requiring mutant of *Lactobacillus casei*[12,21] also lack the enzyme(s) necessary for the conversion.

Consideration of our results led us to the view that the conversion of (III) into riboflavin must be some type of 'dismutation' in which one molecule of (III) yields a 4-carbon unit, or two 2-carbon units, which can combine actively with a molecule of unchanged (III) to produce riboflavin. This can be formally visualized as indicated in reaction (2) (there are other possibilities which will give the same overall result).

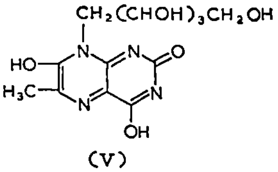
In order to test this hypothesis, we synthesized (III), labelled with carbon-14 in the positions indicated thus ● (see above), by treating 4-ribitylamino-5-aminouracil (IV) with generally labelled carbon-14 acetoin. The generally labelled acetoin was prepared enzymically by using a cell-free preparation (11,000*g* for 1 hr. at 4°) obtained from a sonate of *Acetobacter rancens* 23, which under appropriate conditions will convert pyruvate into acetoin in very high yield (80 per cent)[22]; when [2,3-^{14}C] pyruvate was used as substrate, generally labelled acetoin was obtained.

The 6,7-dimethyl-8-ribityllumazine, labelled with carbon-14 as indicated in reaction (2), was diluted with carrier 6 : 7-dimethyl-8-ribityllumazine and added to a dialysed cell-free preparation of *Candida flareri*; after incubation under optimal conditions for conversion (28° for 3 hr. with constant shaking) the reaction was stopped, carrier riboflavin added and crystalline riboflavin isolated. The radioactivities in this and in the acetic acid obtained from C-6 and C-7 and the attached methyl groups by Kuhn–Roth degradation were assayed as previously described[5]. The results obtained and the values expected if reaction (2) obtains are given in Table 1. They are clearly consistent with the view that (III) liberates enzymically an active 4-carbon unit (or two 2-carbon units) which will combine with (III) to form riboflavin. It is interesting to find that Plaut had come to the same conclusion independently regarding the formation of riboflavin from (III), and he has reported recently an investigation with a partly purified enzyme system which indicates that three molecules of (III) disappear for every one molecule of riboflavin produced[23].

Table 1. Enzymic Conversion of [^{14}C]-6,7-Dimethyl-8-ribityllumazine into Riboflavin in Cell-free Extracts of *C. flareri*. Dialysed cell-free extract of *C. flareri* used with no substrate other than [^{14}C]-6,7-dimethyl-8-ribityllumazine labelled as indicated in reaction 2; incubation for 3 hr. at 28° with continuous shaking

Compound	Specific activity (c.p.m./μmole) Expected	Observed
6,7-Dimethyl-8-ribityllumazine	—	8,000
Riboflavin	16,000	13,200
Acetic acid (from C-6 and C-7 and attached methyl groups)	3,300	3,000

During our experiments on the conversion of (III) into riboflavin, we encountered a secondary product, which shows up as a violet fluorescent spot on chromatography. This is clearly 'compound V' of Masuda *et al.*[24], which has the structure (V). There is general agreement that compound V is not an intermediate between 4-ribitylamino-5-aminouracil and riboflavin[25], but that it is formed as a side-reaction from (III), possibly by reaction of '*X*'



(V)

(reaction 2) with pyruvate[23,24]. If this is so, then it would appear that pyruvate as such is not the condensing unit for production of the aromatic ring of riboflavin. However, it is fairly clear that acetate is not immediately concerned[26], and shikimic acid, the other well-known precursor of aromatic rings[2], is also not involved[27]. It seems likely then that pyruvate gives rise to 'activated acetaldehyde'[28,29], which is incorporated step-wise into (III), or which condenses to form a 4-carbon unit such as acetoin, which combines with (IV) to yield (III). In support of this view it was found that [^{14}C] acetoin ([1-^{14}C]-3-hydroxy-2-butannone) is incorporated into ring *A* of riboflavin with the expected labelling pattern[27]. In this connexion it should be emphasized that the carbon-14 acetaldehyde liberated from carbon-14 threonine by the enzyme threonine aldolase in extracts of *E. ashbyii* is not incorporated into ring *A* of riboflavin[5]; this means either that the acetaldehyde liberated is never 'activated' or that 'activated acetaldehyde' is not concerned with ring *A* synthesis.

Conversion of 6,7-*dimethyl*-8-*ribityllumazine into riboflavin in rat liver.* The fact that riboflavin arises in micro-organisms from purines raises an interesting problem regarding the nature of the metabolic lesion which makes animals dependent on exogenous riboflavin, because all living systems can synthesize the purine skeleton for incorporation into their nucleic acids. It was reported that (III) could be converted into riboflavin by bovine liver preparations[12]; we decided to re-investigate this, using rat liver homogenates. We found that the supernatant from such homogenates centrifuged at 25,000*g* contained a substantial amount of flavin adenine dinucleotide; on incubation this disappeared and free riboflavin appeared. Thus the very high blanks obtained because of the presence of an active flavin adenine dinucleotidase in our preparation made it impossible to decide whether (III) was converted into riboflavin or not. This can be decided finally only by using [^{14}C]-6,7-dimethyl-8-ribityllumazine followed by enzyme purification. Katagiri *et al.*[12] did not comment on this possibility of riboflavin formation in the report of their work on bovine liver extracts.

We wish to thank Dr. T. Masuda for a gift of 6,7-dimethyl-8-ribityllumazine, Prof. J. de Ley for a culture of *Acetobacter rancens* 23, Dr. B. G. Audley for collaboration in certain experiments, the Agricultural Research Council for financial assistance (T. W. G.) and the University of Liverpool and University of Wales for personal grants (A. A. H.). The sonic disintegrator used was purchased with a grant from the Royal Society. Part of this work was carried out in the Biochemistry Department, University of Liverpool.

ESSENTIAL OIL FROM FRESH *CANNABIS SATIVA* AND ITS USE IN IDENTIFICATION

By L. MARTIN
The Commonwealth Laboratories, 415 Flinders Lane, Melbourne
AND
D. MORISON SMITH and C. G. FARMILO
The Laboratories of the Food and Drug Directorate, Department of National Health and Welfare, Ottawa, Ontario

THE two main natural narcotics found in the illicit international traffic are opium and *Cannabis*. Considerable research has been done to develop methods of identifying and estimating opium constituents, and correlating these results to determine the country of origin[1-3]. A similar collaborative research programme has been inaugurated under the auspices of the Commission on Narcotic Drugs of the Economic and Social Council of the United Nations at Geneva, as an aid to tighten international *Cannabis* control measures[4]. Present methods of identification of *Cannabis* are based on botanical features, and colour and ultra-violet absorption tests on petroleum ether extracts of the plant or its resin. Since the tests are not satisfactory for forensic purposes, investigation of methods of *Cannabis* identification were begun by Farmilo *et al.*[5,6].

On the basis of previous experience in this laboratory[7,8], essential oils have been shown to be useful in plant characterization and origin determination. For this work thirteen samples of male and female fresh *Cannabis sativa* L. (the samples were identified

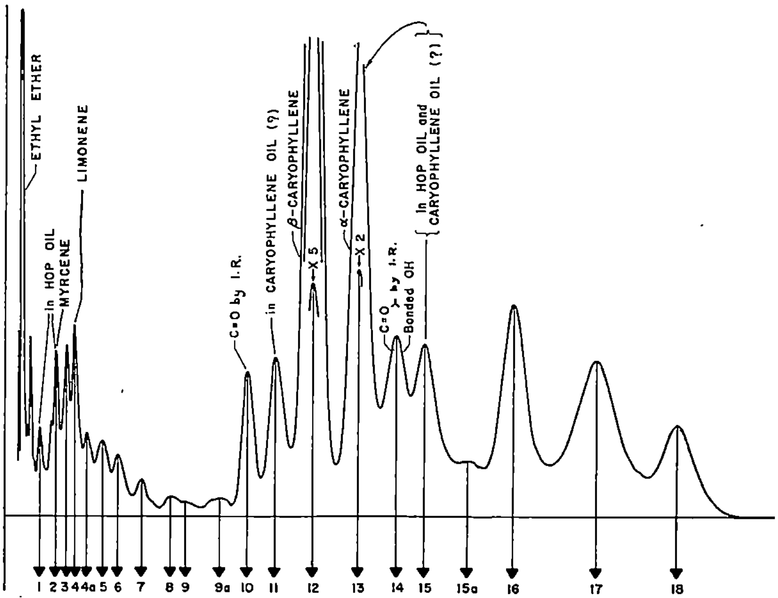

Fig. 1. Gas chromatogram. Oil from fresh large leaves of female *Cannabis sativa* (L.) Source: wild growth, Eastview, Ontario

botanically by Dr. D. Frankton, head of the Taxonomy Group, Weed Investigation Section, Plant Research Institute, Research Branch, Department of Agriculture; specimens are stored for future reference in the Arboretum of the Central Experimental Farm, Ottawa) found growing wild in ten different locations of the Canadian Provinces of Ontario and Quebec were used. (The samples of fresh *Cannabis* were provided through co-operation of the Narcotic Control Division, and the Royal Canadian Mounted Police, to whom we are indebted for this help.) The plants were stripped of leaves and inflorescences and the parts analysed separately. In addition, samples of dried *Cannabis*, hashish and charas of several different origins were studied. Hop oil and caryophyllene oil (courteously and generously supplied for this work by Fritzsche Bros., Inc., New York: the caryophyllene is produced from *Balsam copaiba* by washing and by fractionation) were used as references for characterization purposes.

Steam distillation of fresh male and female *Cannabis* plants at various stages of maturity yielded 0·05–0·11 per cent of oil (female and more mature specimens show highest yields). These results compare well with previous findings[9]. Gas chromatographic analysis of the oil (5 µl.) was carried out using a helium carrier gas-flow (75 ml./min.) through a column (2·5 m.) packed with 'Apiezon *M*' grease (20 per cent) supported on 'Chromasorb *W*' heated to approximately 220° C. More than thirty samples of oils have been assayed in this manner.

On one large oil sample, fractions corresponding to the constituents separated during gas chromatography were collected in small glass tubes packed loosely with glass wool, which were fitted on the exit end of the gas-chromatographic column. These fractions were dissolved in carbon tetrachloride and infra-red spectra were obtained using a Perkin Elmer Model 21, equipped with a scale expansion device and sodium chloride cavity cells (30 µl. capacity). After evaporation of the carbon tetrachloride solutions, the residues were redissolved in ethanol for application of colour and ultra-violet spectral tests. The spectra were taken in cells of 1 ml. capacity and 1 cm. path-length using a Beckman *DK*2 ratio recording spectrophotometer. The spectra of the neutral, acidic and basic ethanolic solutions were obtained. The colour tests, alkaline beam (ethanolic potassium hydroxide solution), Duquenois (vanillin and acetaldehyde in ethanol plus hydrochloric acid) and the Ghamrawy (*p*-dimethylaminobenzaldehyde in concentrated sulphuric acid) were carried out on a few drops of the ethanolic solution of each fraction.

The results of the above experiments are illustrated by the data given in Table 1 and a typical gas chromatogram is shown in Fig. 1. Table 1 lists the relative retention-time values (RRT-values) and the relative percentage composition of four oil samples obtained from leaves and inflorescences of fresh immature male and female plants picked in Eastview, Ontario. The illustration shows the gas chromatogram of the oil obtained from the large leaves of the female plant described.

A detailed examination of the chromatograms from the thirty *Cannabis* oil samples has shown remarkable consistency and reproducibility in the RRT-values of all peaks of the constituents 1–18. In comparing the RRT-values of one chromatogram with those of another a difference of 5 per cent in the values is taken arbitrarily as indicating a new component. Small peaks, such as those indicated by the numbers 4*a*, 9, 9*a*, and 15*a* are not always significant peaks in other chromatograms, and may vary in height and area depending on the part of the plant from which the oil is taken, for example, leaves, tip leaves, flowers, seed pods, etc. The roots and stems of the plants did not yield oil. The peaks 1–5 and those from 10 to 18 are thought to be most useful for the characterization of the oil of *Cannabis*.

* Peaks present, but too small to be measured.

The essential oil of *Cannabis* resin (called either hashish or charas, if the source is either Eygpt or India respectively) has long been known to contain terpenes and sesquiterpenes which boil at temperatures much lower than the physiologically active narcotic constituents, tetrahydrocannabinols. The complexity of the composition of this oil has never been realized before, nor would it have been practical to assay it without the aid of gas chromatography. Simonsen and Todd[11] state that the essential oil from hashish consists mainly of *p*-cymene, 1-methyl-4-*iso*propenylbenzene and humulene (α-caryophyllene). They were not able to identify the presence of myrcene in hashish, although Wood, Spivey and Easterfield[12] had much earlier found it in charas from *Cannabis indica* (syn. *sativa*) obtained from Etawah in the province of Uttar Pradesh in India. By comparison of the RRT-values from the gas chromatograms of the oil of hops, another member of the family Moraceae, and of caryophyllene oil, peaks 2 and 4 are identified as myrcene and limonene respectively. β- and α-caryophyllene are found to be peaks 12 and 13. A number of other bands, 1, 2, 11 and 15, may be present (the same RRT-values) in the hop oil chromatograms and should be relatively easily identified for this reason. Infra-red spectral data indicate that the other compounds of terpenoid character show distinct functional groups, for example, hydrogen-bonded OH and C = O vibrations are evident. Others have aromatic characteristics which are revealed by their infra-red and ultra-violet spectra. More rigorous characterization of the remaining unidentified bands is now being carried out.

Chromatograms of oils from dried *Cannabis*, hashish and charas show distinct differences from those of the fresh oils.

The alkaline-beam colour test is stated to be positive when cannabidiol is present[13] and is given by some of the crude oils prior to fractionation on the gas chromatograph. No positive beam-test was obtained with any of the fractions isolated by means of gas chromatography. The Duquenois test is given by both α- and β-caryophyllene fractions; however, the former may react more strongly with this reagent. The question of concentration differences remains to be settled. The Ghamrawy reagent appears to be the least selective in its reactivity, the orange-red colour being given by fractions 10, 11, 15, 16, 17, 18. After dilution with water the colours in these tests changed to the characteristic blue colour. When applied to the original petroleum ether extracts of the plants of *Cannabis*, the alkaline-beam test is not always positive. The Duquenois and Ghamrawy tests have always been positive. It is therefore quite possible that the latter indicate the presence of the two caryophyllenes.

In conclusion, we wish to state that the fourteen peaks which are constantly present in the gas chromatograms of the oil serve to characterize, beyond a reasonable doubt, fresh, green *Cannabis sativa* L. found in Quebec and Ontario. Dried *Cannabis*, charas and hashish may also be distinguished and characterized on this basis. There are further useful chemical differences which help to identify them.

INDUCTION OF MUTATIONS BY DEOXYRIBONUCLEIC ACID IN *DROSOPHILA MELANOGASTER*

By DR. O. G. FAHMY and DR. MYRTLE J. FAHMY

Chester Beatty Research Institute, Institute of Cancer Research : Royal Cancer Hospital, London, S.W.3

THE genetic activity of deoxyribonucleic acid (DNA) was conclusively demonstrated by the phenomenon of bacterial transformation[1,2], mainly in the genera *Diplococcus* and *Haemophilus*. When a genetically marked strain was exposed to DNA extracted from another with different genes, a new combination occurred in the recipient through the incorporation of one or more of the donor loci. A parallel phenomenon is that of transduction, which was demonstrated in *Salmonella*[3,4], where heritable changes of bacterial characteristics were brought about by bacteriophage-carried material assumed to be DNA. The consequences of administration of DNA in higher organisms has, so far, been a subject of conflicting reports. A phenomenon akin to bacterial transformation was reported in ducks by the Benoit group[5-7], but subsequent experimentation[7,8] failed to confirm these results. In mammals efforts to induce 'somatic transformation' have all failed[9,10].

For the investigation of the genetic consequences of DNA administration, *Drosophila* is a favourable test system. Techniques are available for the detection of mutations as well as induced transformation at specific loci. Both these aspects have been studied and the results are presented in this communication. While no specific gene replacement (locus transformation) was observed, the mutation-rate (especially as regards *Minutes*) was raised significantly above the control-level.

The DNA utilized in the present experiments was prepared in the Chester Beatty Research Institute; the first sample was extracted by Brookes from adults of the wild type strain (Oregon-*K*) of *Drosophila melanogaster*, according to Kirby's *p*-aminosalicylate/phenol method[11]. The DNA yield was extremely low and although free from RNA and protein, was in admixture with some unidentified impurities, probably polysaccharides. It was thought possible that the impurities might have been derived from the adult's chitinous exoskeleton, and accordingly attempts were made to extract DNA from embryonic tissue, namely, developing eggs. A method was devised for the production of eggs *en masse*, which enabled the collection of 2–3 gm. of pre-larval embryos per week, from a population of about 50,000 flies. The extraction of DNA from embryos was undertaken by Kirby by a modification of his previously published method[11]. This involved the breaking down of the tissues with diethyldithiocarbamate and phenolphthalein diphosphate before the application of phenol[12]. The percentage base ratio for a typical sample of the DNA separated by this method[12] was: guanine 23·8, adenine 29·3, cytosine 18·5, thymine 28·4. A sample of heterologous DNA from rat liver was also tested. This was prepared by the *p*-aminosalicylate/phenol method and gave nearly the same percentage base ratio[13] as the *Drosophila* sample (guanine 21·3, adenine 29·1, cytosine 20·1, thymine 29·5).

A cell-free extract of embryonic tissue was also tested for mutagenicity. This was prepared as follows: 1 gm. of eggs (pre-larval embryos) were mixed with 0·4 gm. of solid sodium chloride, and thoroughly ground in a glass homogenizer surrounded by solid carbon dioxide. The tissue homogenate was then diluted with 100 ml. of distilled water (to make the salt concentration isotonic) and filtered through glass wool. The filtrate was examined microscopically and proved to be a suspension free from whole cells and intact chromosomes. The concentrated salt treatment used probably disrupted the DNA/histone linkages, so that the above suspension might be looked upon as a dilute solution of DNA in admixture with other cell constituents.

The various samples of DNA were dissolved in isotonic saline (0·4 per cent sodium chloride) at the desired concentration (0·1–1 per cent) and the solutions were injected into the hæmocœl by our micro-injection technique[14]. For the mutagenicity tests wild-type (Oregon-*K*) males were treated and their progeny was scored for mutations. Chromosome fragments and visible mutations (autosomal dominants and sex-linked recessives) were tested for by the attached-*X* technique, and the sex-linked recessive lethals and visibles by the Muller-5 method[15]. In the transformation experiments, multiple recessive stocks were used carrying either 3 or 7 markers. Flies from these stocks were injected with a DNA solution extracted from the wild type, which would be derived from the full gene complement, including the normal alleles of the mutant markers. If any marked locus were substituted by the normal allele from the administered DNA, the phenotypic expression, corresponding to the substituted (transformed) locus, would be expected to revert to the wild type.

In both the mutagenicity and transformation experiments the progeny of the treated males was fractionated into 3-day broods by our standard technique[15]. Breeding was undertaken in mass-cultures with roughly equal male to female ratio.

The most convincing mutagenic effect of DNA treatment was the considerable increase in the rate of *Minutes* above the control-level (Table 1), which proved to be very highly significant in all experiments (Table 3). These mutations are a large class of non-allelic genotypic changes of comparable phenotype, expressed as various degrees of reduction in the length and thickness of the thoracic macrochætes. In extreme cases, the bristle effect is accompanied by various anomalies of the eyes as well as the wings (especially as regards venation). *Minute* mutants have a longer period of development, and are accordingly late in eclosion. They are dominant and lethal in the homozygous condition and are frequently demonstrable as deficiencies or small deletions in the salivary-gland chromosomes[16]. At the highest injected dose (1 per cent homologous sample, Table 1) the induced rate of *Minutes* was higher than the controls by a factor of nearly 12, while at the lower doses (with both the homologous and heterologous samples) the increase was by a factor of 2–3. The data from the homologous samples suggested that there might be a direct dose-effect relationship (Tables 1 and 3). In contrast to the situation with the *Minutes*, other induced F_1 autosomal dominants were rare, and were not significantly above the control-level; they were, accordingly, excluded from the present analysis.

The yield of the sex-linked recessive visibles in the treated series was also raised above the control-level both in the F_1 and F_2 experiments (Tables 1 and 2). For a statistical assessment of this trend, a certain amount of pooling of the data was undertaken to overcome the extreme rarity of visible mutations. The normal and mutant chromosomes in the F_1 and F_2 experiments for the control and treated series (from the same DNA sample and dose) were summed and compared in 2 × 2 contingency tables, and the results are given in Table 3. This analysis established the statistical significance of the increase in the visible rate with the high-dose experiments. The visibles from all experiments were subjected to allelism tests. The specific loci so far identified are listed here in their chromosomal order.

Control: *yellow* (*y*), *white* (*w*), *ommatoreductum* (*omm*), *dusky* (*dy*), *rudimentary* (*r*), *forked* (*f*).
Homologous DNA: *yellow* (*y*), *broad* (*br*), *stubs* (*sbs*), *pebbled* (*peb*), *tenuous-bristles* (*tnb*), *vesiculated* (*vs*), *smaller* (*sma*)-2, *vermilion* (*v*), *costakink* (*csk*), *miniature* (*m*), *narrow-scoop* (*nrs*), *fused* (*fu*).
Heterologous DNA: *brachymacrochaete* (*brc*), *white* (*w*), *rugose* (*rg*), *carmine* (*cm*), *copper* (*cop*), *rudimentary* (*r*)-2, *forked* (*f*)-2, *bronzy* (*bz*).

It would seem probable, therefore, that DNA treatment simply increased the incidence of mutation at the more responsive loci which occasionally mutated spontaneously. One point of interest, however, is that the *broad* (*br*), *rudimentary* (*r*), and *bronzy* (*bz*) mutants proved to be of the non-complementing[17] type, suggesting that the damage extended over all the cistrons of these complex loci. This may be an indication of the large size of genic damage by DNA, which of course is clearly suggested by the induction of *Minutes*.

The administration of DNA does not seem to result in a dramatic increase in the rate of the sex-linked recessive lethals (Table 2). Nevertheless, in one of the high-dose experiments (1 per cent DNA from adults, Table 3) there was a significant increase in the rate of these mutations above the control-level. It would seem probable, therefore, that larger scale experiments might permit a conclusive demonstration of the induction of recessive lethals by DNA.

Mutagenesis studies of the fractionated progeny of males treated with various alkylating agents enabled the assessment of the time of sampling of the various stages of the testis in the brood-technique used in the present experiments. The post-spermatogonial stages (sperm, spermatids and spermatocytes) are predominantly utilized in the first four broods 0–12 days after treatment, whereas the spermatogonia are mainly recovered in the fifth and later broods (cf. ref. 18). In the light of the above conclusion, it is possible to infer the stages of spermatogenesis most susceptible to mutation by DNA. In practically all the experiments and with all the mutations scored (especially the *Minutes*), the maximal mutation-rate occurred in the first or second brood. There was one exceptional experiment (0·2 per cent homologous sample, Table 1) where the maximal rate (as regards *Minutes*) occurred in the third brood; but in no instance did the peak of mutability occur beyond the fourth brood. It is therefore certain that maximal mutagenicity by DNA occurs in mature sperm or late spermatids and minimal effect is on the earlier sperm mother cells, especially the spermatogonia. It should be pointed out, however, that even spermatogonia are not completely refractory to DNA; the rate of *Minutes* in the late progeny (fifth brood onwards) proved to be significantly greater than that in corresponding progeny fractions among the controls.

The DNA samples used in the above mutagenicity tests were extracted by procedures involving the utilization of compounds (such as phenol) which may not be mutagenically inert. Although it is virtually certain that none of these reagents was left in the purified DNA samples, it was felt desirable to ascertain the mutagenicity of DNA in the absence of such reagents. A cell-free tissue extract (in which the DNA/protein linkages were disrupted by concentrated salt) was accordingly subjected to an attached-X test. The injected suspension proved to be extremely toxic to the treated males, but it was possible to recover a single brood, containing 4,299 F_1 patriclinous males. In this sample 11 *Minutes* were scored—a rate of 2·55 per thousand, which proved to be significantly higher than the control-level ($\chi^2{}_{(1)} = 10{\cdot}0$; $P = 0{\cdot}001$).

The mutation-rate (as regards *Minutes*) induced by the tissue extract (1 gm. embryonic tissue in 100 ml. saline) was of the same order of magnitude as that induced by 0·2 per cent solution of pure DNA extracted from developing eggs (Table 1). If the mutagenic activity were entirely due to the DNA content of the tissue extract, the biological results would require the presence of 200 mgm. of DNA per gram of embryonic tissue; whereas in fact the extraction yield in Kirby's experiments was approximately 2–3 mgm. per gram of developing eggs[12]. This might be an indication that the mutagenic efficiency of 'native' DNA was partially impaired by the phenol extraction procedure. Alternatively, it could suggest that the cell extract contained ingredients (such as nucleohistones or RNA) which contributed to the induction of *Minutes*. This problem is now under investigation.

The experimental details of the attempts at transformation of specific loci are given in Table 4. A multiple recessive stock was injected with DNA extracted from the wild type and the F_1 progeny was scored for reversion (transformation to the wild-type phenotype) at the various loci in the stock. In one experiment (1 per cent DNA from adults, Table 4) three autosomal markers were used: *brown* (*bw*: II), *ebony* (*e*: III), *poliert* (*pol*: IV), and only the male parents were injected with the DNA solution. In later experiments a stock with seven markers was used; *X*-chromosome with four mutations—*yellow* (*y*), *vermilion* (*v*), *miniature* (*m*), *forked* (*f*)—was incorporated in the gene complement together with the above three autosomals. A high concentration of DNA (1 per cent solution from embryos, Table 4) was injected either into both parents or into the male parent only. When injection was restricted to the fathers, only the number of the F_1 daughters was taken to represent the frequency of the potential transformants at the sex-linked loci. This precaution was taken in case a close association between the DNA and the treated chromosome is a pre-requisite of transformation. The high DNA concentrations had strong toxic and sterilizing effects on the treated flies, which prevented the recovery of large progeny. To overcome this difficulty, a low DNA dose was used and only the males were injected (0·2 per cent solution from embryos, Table 4) and this permitted a much larger test.

Table 4. NUMBER OF F_1 PROGENY OBSERVED FOR TRANSFORMATION AT SPECIFIC LOCI, AFTER TREATMENT WITH DNA FROM THE WILD TYPE

Sex injected	Females and males	Males	
Loci tested	*y v m f bw e pol*	*y v m f*	*bw e pol*
DNA sample			
1 per cent (adults)	—	—	1,185
1 per cent (embryos)	3,397	1,596	2,954
1 per cent (embryos)	99	757	1,547
0·2 per cent (embryos)	—	32,182	63,053
Total	3,496	34,535	68,739

As can be seen from Table 4, an overall total of 72,235 individuals was examined for transformation at the three autosomal loci, and 38,031 at the four sex-linked genes, but none was transformed to the normal allele. Any further increase in the size of sample would probably have involved the occurrence of spontaneous back mutation, which of course would not have been distinguishable from transformation. The present data, therefore, could reasonably be considered as strong negative evidence against the occurrence of specific locus transformation in *Drosophila*.

The exact mechanism whereby the injected DNA produces small chromosome deletions (*Minutes*) is difficult to interpret. Direct action through the induction of chromosome breaks as occurs with radiation can be safely excluded. The experiments were designed to reveal any viable chromosome fragments induced, but none was actually observed (in a sample of 83,893 scored females), indicating that the DNA treatment does not disrupt the polynucleotide chain of the chromosome. With the highly reactive alkylating agents, it was possible to show[19] that the induction of small deficiencies was not always correlated with chromosome breakage, but could also result from gene inactivation *in situ*. With DNA, however, it is virtually certain that neither the molecules themselves nor their degradation products could possess any alkylating ability to induce direct damage in the hereditary nucleoproteins.

It would seem, therefore, that mutations induced by DNA are the result of an indirect mechanism involving errors in chromosome replication, either during germ-cell multiplication or subsequent to fertilization during cleavage. Mitoses in the germ line do not appear to influence the mutation yield, since the effect of DNA treatment was higher on sperm and spermatids than on proliferating spermatogonia. However, this could be due to secondary factors such as a lower initial uptake of DNA, or a more rapid rate of its degradation by the cytoplasmic DNase in spermatogonia. It is reasonable to assume, therefore, that DNA incorporated in the germ cells at the time of treatment (especially in mature sperm), is passively transferred in association with the male chromosome complement to the zygote, and mutant induction actually occurs during chromosome replication at the first cleavage. An important feature of the phenomenon is that it appears to be non-specific: both as regards the inducing DNA (whether homologous or heterologous) and the induced mutations (predominantly non-allelic *Minutes*). The induction process, therefore, does not necessitate a specific exchange (akin to crossing-over) between the exogenous DNA and a particular locus on the chromosome, as was postulated[2] for bacterial transformation.

We are grateful to Prof. A. Haddow for his interest, to Prof. P. C. Koller for reading and criticizing the manuscript and to Dr. K. S. Kirby and Dr. P. Brookes for the preparation of the DNA samples tested.

This investigation has been supported by grants to the Chester Beatty Research Institute (Institute of Cancer Research: Royal Cancer Hospital) from the Medical Research Council, the British Empire Cancer Campaign, the Jane Coffin Childs Memorial Fund for Medical Research, the Anna Fuller Fund and the National Cancer Institute of the National Institutes of Health, U.S. Public Health Service.

PROPERTIES OF ISOLATED PLANT PROTOPLASTS

By E. C. COCKING

Department of Botany, University of Nottingham

LIBERATED bacterial[1] and fungal[2] protoplasts have proved to be of unique value in morphological, biochemical and genetic work on these micro-organisms. Following the recent demonstration in this laboratory[3] that plant protoplasts can be liberated from root cells of *Lycopersicum esculentum* after digestion of the cell walls by the enzyme cellulase, investigations into the properties of these liberated plant protoplasts have now indicated their unique potentiality for similar studies.

Protoplasts were liberated from root tips of tomato seedlings (*Lycopersicum esculentum* Mill. var. Sutton's Best of All) by treatment with *Myrothecium* cellulase[3]. Seedlings were grown under aseptic conditions and 3-mm. root tips from roots 20 mm. in length were used. The root tips were incubated at 27° C. for 2 hr. with freshly prepared *Myrothecium* cellulase in a 0·6 *M* sucrose modified White's culture medium[4] at *p*H 4·5. After treatment, the root tips were washed free of cellulase and mounted in special micro-culture chambers[5] in which liberated protoplasts could be examined microscopically, while freely suspended in the culture medium.

In the first experiment (exp. 1) root tips treated with cellulase were mounted in 0·6 *M* sucrose White's medium and microscopic measurements made of changes with time of protoplast and vacuole diameters. Most of the liberated vacuolated protoplasts were stable for about 12 hr. in this medium at room temperature; however, a few (approximately 1 per cent) burst after about 1 hr. Changes in protoplast and vacuole diameters of one of these rapidly bursting vacuolated protoplasts are shown in Table 1. The densely protoplasmic protoplasts which showed little evidence of vacuolation were stable over a period of several days, when maintained in a similar medium. During this time, they showed a slight tendency to shrink; they became opaque and the outer membrane became more clearly defined.

In exp. 2, 3-mm. root tips of tomato seedlings grown and treated with cellulase under similar conditions to exp. 1 were mounted in micro-culture chambers containing a 0·6 *M* sucrose White's medium at *p*H 4·5 with 10^{-5}, 10^{-7}, 10^{-9} and 10^{-11} gm./ml. of 3-indolylacetic acid (IAA, Kodak). There was a very rapid bursting of vacuolated protoplasts. The most rapid and extensive bursting took place at 10^{-11} gm. IAA/ml. of 0·6 *M* sucrose White's medium and within 1 min. of treatment no vacuolated protoplasts or vacuoles could be observed. The least rapid bursting took place with 10^{-5} gm. IAA/ml. and changes in protoplast and vacuole diameters of one of these vacuolated protoplasts are shown in Table 2. There was not only a very rapid increase in the size of existing vacuoles present in the protoplasts, but also formation of new vacuoles both in already vacuolated protoplasts and in densely protoplasmic protoplasts. At an early stage in their development these vacuoles were more gel-like in nature and less rounded than existing vacuoles. When these vacuoles were liberated at this early stage of development, it was noted that the tonoplast was less clearly defined than in previously isolated more mature vacuoles. No inclusions were present in these vacuoles induced by IAA. Figs. 1 and 2 show typical changes in vacuolar form induced by 10^{-5} gm. IAA/ml. over a period of 3 hr. at room temperature. Photomicrographs were taken using a Leica camera and attachment mounted on a Baker series 4 microscope with a fluorite (× 100) phase-contrast oil immersion objective and 'Trilux' condenser. More rapid changes in vacuolar form were induced by lower concentrations of IAA, but photography of these was more difficult, due to the fact that marked changes took place during the required exposure time of 25 sec. A typical gel-like, mobile vacuole is shown in Fig. 1 (*A*); its formation was associated with active movement of the protoplasm and its associated granules.

† Gel-like, mobile vacuole. Measurements on this vacuole were only possible after bursting of the protoplast.

‡ No measurements taken.

Further cultural studies of protoplasts were carried out using specially prepared tomato root extract. This extract was prepared by homogenizing twenty 20-mm. roots in an all-glass homogenizer under aseptic conditions with 0·5 ml. 0·6 *M* sucrose White's medium at *p*H 4·5. Liberated protoplasts were cultured in this whole homogenate in the special micro-culture chambers previously described. Chambers were sealed with heavy mineral oil (paraffin liq.

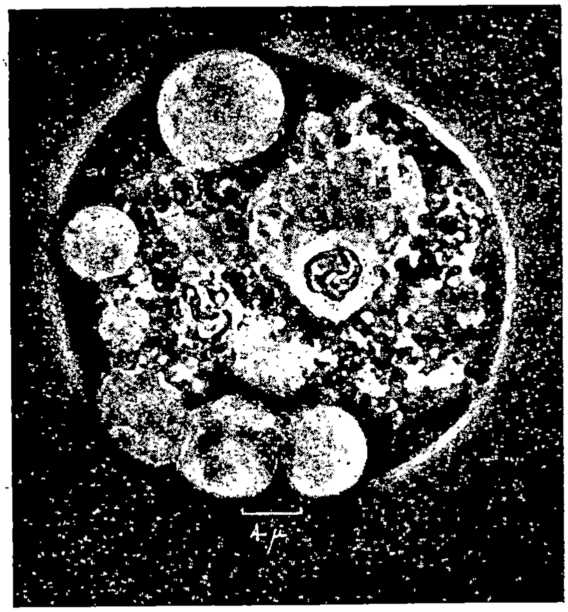

Fig. 2. Vacuolated protoplast (phase contrast). Treated with 10^{-5} gm. 3-indolylacetic acid/ml., 0·6 M sucrose White's medium for 3 hr. 15 min.

B.P. (Boots) to United States Pharmacopœia requirements), and under these conditions protoplasts could be maintained under aseptic conditions for at least one week (exp. 3). After culture for one day at room temperature, there was evidence of a more definite membrane around the more densely protoplasmic protoplasts. Furthermore, it was observed that several of these protoplasts had produced a bud-like protrusion (Fig. 3) after culture for two days in this tomato root extract; these protoplasts had by this time become highly opaque with particulate material massed near the surface of the now clearly defined outer membrane. These budding, densely protoplasmic structures closely resemble the budding cells observed[6] among single cells cultured in the presence of coconut milk. The implications of this finding will be discussed later.

It is known that mannitol[7] only very slowly penetrates into plant cells. Experiments were therefore carried out using mannitol as the osmotic stabilizer to determine whether the changes in opacity and membrane characteristics of these protoplasts observed in exps. 1 and 3 were being brought about by a toxic action of sucrose at the high molarity (0·6 M) necessarily used to maintain osmotic equilibrium in the culture medium. Protoplasts were cultured in 0·06 M sucrose, 0·54 M mannitol White's medium at pH 4·5. Changes in the opacity and membrane characteristics were observed similar to those in exps. 1 and 3. When comparable densely protoplasmic protoplasts were maintained in 0·6 M mannitol White's medium at pH 4·5 in the absence of sucrose, no such changes, however, could be observed. It would therefore seem highly probable that these changes are specific and are associated with sucrose metabolism and possibly cellulose synthesis.

These results indicate clearly the potentiality of the study of plant protoplasts in elucidating many of the present problems associated with growth and differentiation in plants. Owing to the absence of the cell wall, the response to nutrients and growth substances known to effect the growth and development of the whole root may be investigated at the protoplast-level with a greater attention to cytological detail and behaviour than has hitherto been possible with living cells. Moreover, the absence of the cell wall enables a more direct analysis of the mechanisms underlying these responses to be made. The protoplasmic effects of 3-indolylacetic acid and their possible association with increased water uptake by plant cells have recently been emphasized[8]. Other workers have focused their attention mainly on changes in the plasticity of the cell wall and possible chelation action of 3-indolylacetic acid[9-12]. Important as these effects on the cell wall may be, it is clearly possible to relate any effects of 3-indolylacetic acid observed with these protoplasts entirely to protoplasmic effects, and to effects on the plasmalemma and tonoplast. In view of the viscosity changes induced in vacuoles by 3-indolylacetic acid and observed in the present work, and the marked protoplasmic effects, it would seem that the application of simple osmotic relationships to explain the behaviour of these protoplasts in terms of vacuolar swelling may not be directly

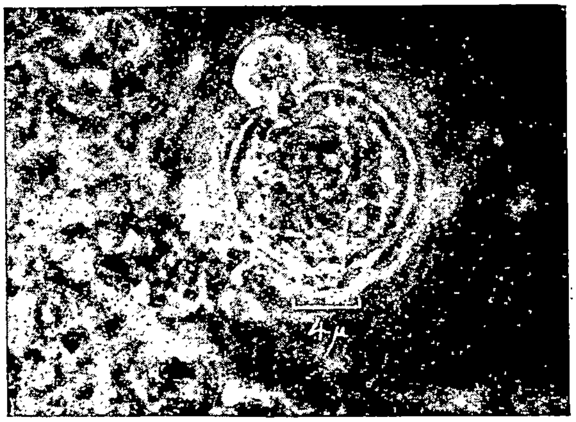

Fig. 3. Budding 'protoplast' (phase contrast)

possible. The study of the osmotic behaviour of mechanically isolated clearly defined vacuoles[13] may yield little information concerning the actual osmotic relationships of vacuoles *in vivo* as they are induced and develop under the action of 3-indolylacetic acid and other similar growth-substances.

Budding of both highly vacuolated[6] and densely protoplasmic[14] cultured single cells has been reported. It has also been established that these 'buds' can become independently growing cells either separating from, or remaining attached to, the 'mother cell'[6] provided that this cell is highly vacuolated. In the case of budding densely protoplasmic cells, division of the 'mother' cell nucleus has been observed, resulting in the formation of a binucleate cell but the 'buds' in this instance do not seem to have a separate existence from the 'mother cell'. It is of some significance that densely protoplasmic structures with buds have been seen to be formed from densely protoplasmic protoplasts, when these were cultured in a White's medium tomato root extract, which probably contains many of the growth-substances associated with the White's medium supplemented with whole coconut milk as used in the culture of budding cells[6,14]. It seems likely that these protoplasts first develop some form of primary cellulose wall and then, parallel to their later development, they acquire some aspects of the behaviour of freely suspended isolated cells[6]. Clearly, further work with coconut milk and culture media supplemented with mannitol will be required before more definite answers can be given to the many questions arising from these new findings.

McQuillen[15] has noted that the optical density and dry weight of *Bacillus megaterium* protoplasts increases during incubation in suitable media, but that reversion to a bacillary form rarely, if ever, occurs. It is suggested that reversion only occurs when a trace of original wall material is still present, which can act as a primer or 'starter' for synthesis of new cell-wall material. These densely protoplasmic plant protoplasts are known to arise from meristematic cells in which the cell wall is very intimately associated with the protoplasm[3], and it may be of some significance that signs of reversion to a cellular form mostly occur among protoplasts such as these.

During the course of the present investigations, it was repeatedly possible to observe separated vacuoles, nuclei and masses of granular protoplasmic material following osmotic bursting of protoplasts. The development of osmotic bursting as a mild procedure for the separation and ultimate fractionation of protoplasmic components has been rendered difficult by the instability of these components arising as a result of the osmotic changes. The demonstration in the present work of the bursting ability of 3-indolylacetic acid is being utilized for the separation of protoplasmic components, since it is now possible to induce bursting of protoplasts in 0·6 *M* sucrose White's medium without changing the osmotic environment.

Thanks are due to Miss O. Wright for expert technical assistance. The award of a grant-in-aid from the Royal Society and a research grant from the Department of Scientific and Industrial Research is gratefully acknowledged.

TUBER BULKING IN THE POTATO CROP

By R. W. RADLEY, M. A. TAHA and P. M. BREMNER
Department of Agriculture, University of Nottingham

YIELD in the potato crop is the resultant of the rate and duration of tuber bulking, the latter being a function of the time of tuber initiation and persistence of foliage. There is little precise information concerning the relative importance of these factors in accounting for differences in yield between varieties and different husbandry practices, and results obtained from field experiments at Sutton Bonington in the 1960 season may therefore be of interest.

Fig. 1 shows the course of leaf area development and tuber bulking, as revealed by weekly sampling, in Arran Pilot (the most widely grown early variety), Majestic (the most widely grown main crop) and Ulster Torch (a main crop, sometimes grown as an early, which is notable for its resistance to blight), planted on April 13.

The curve for increase in tuber weight with time, though similar in form, is displaced in time relative to that obtained by Borah and Milthorpe[1], and conflicts with the view that tuber initiation occurs near the time of maximum leaf area, and that the

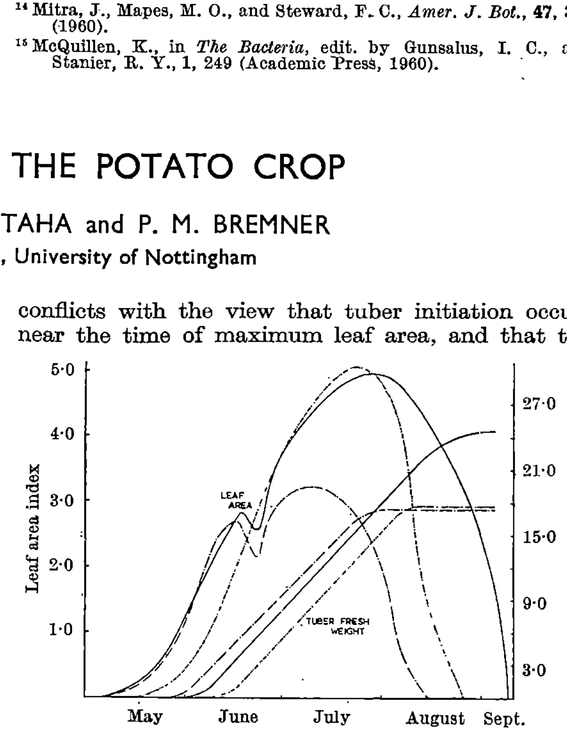

Fig. 1. Leaf area index and tuber growth in three varieties. ——, Ulster Torch; —···—···, Majestic; —·—, Arran Pilot

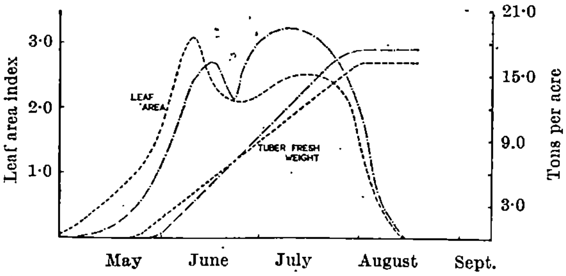

Fig. 2. Leaf area index and tuber growth in Arran Pilot planted on two different dates
– – –, Planted March 28; —·—, planted April 13

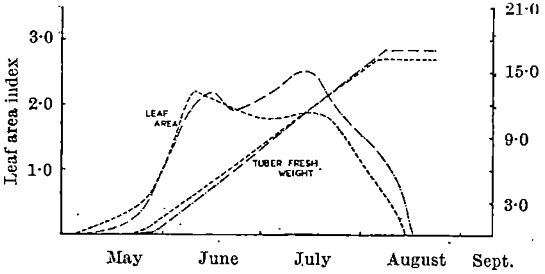

Fig. 3. Leaf area index and tuber growth in Ulster Chieftain planted on two different dates
– – –, Planted March 28; —·—, planted April 13

growth of tubers occurs at a time when leaf area is decreasing. In each variety the major part of tuber growth is made before maximum leaf area ; indeed, decline in leaf area by senescence (as in Arran Pilot) or by blight (as in Majestic, and later Ulster Torch) is followed in about 14 days by the cessation of tuber bulking. The same general picture emerges with other varieties included in these experiments (Figs. 2 and 3). It should be noted, too, that though departures from linearity during the main period of bulking are generally small ($r = 0·98$), they may be considerable when growing conditions are adverse : in the very dry 1959 season, particularly where inter-plant competition was intense, as with closely spaced plants, there was a mid-summer decline in leaf area and an almost complete cessation of tuber bulking. Subsequent recovery in leaf growth was associated with an increase in tuber weight.

Consideration of Fig. 1 suggests that tuber bulking-rate (here considered to be the slope of the curve during the linear phase) is, within fairly wide limits, independent of leaf area. On the other hand, Figs. 2 and 3 indicate that there may be a relationship between the two parameters, in so far as higher bulking-rate is associated with greater leaf area. The apparent discrepancy may possibly be due to leaf development in Ulster Torch and Majestic having surpassed the 'ceiling' at which crop growth-rate declines because of mutual shading of leaves. The pattern of total dry matter production in Arran Pilot and Ulster Torch is consistent with this hypothesis : there was no difference in this respect between the two varieties below leaf area index of 3, and little difference when the leaf area index of Ulster Torch increased to 5 while that of Arran Pilot remained at 3. This would suggest that there is no intrinsic difference between the varieties with regard to net assimilation-rate, but that the rate of Ulster Torch later declined relative to that of Arran Pilot because of the greater degree of mutual shading of leaves in the former variety.

Regarding the relative importance of the rate and duration of bulking in accounting for yield differences, Fig. 1 illustrates the paramount importance of the latter with these particular varieties in the 1960 season. By virtue of tuber initiation two weeks earlier, Arran Pilot had a yield advantage over Majestic of 4·4–4·8 tons per acre during the linear phase of bulking, but its final yield was slightly less because of earlier leaf senescence. Similarly, Ulster Torch had an advantage of 2·7 tons per acre over Majestic until the beginning of August, and gained a further 4·3 tons per acre afterwards, because of its blight resistance, which resulted in persistence of foliage for some 2–3 weeks after Majestic had virtually no green tissue. In contrast, differences in bulking-rate would appear to be of minor importance : with the exception of Ulster Chieftain (an early), which had a significantly lower bulking-rate than all others, varieties differed little in bulking-rate when planted at a time regarded as optimal for main crops (April 13.)

While duration of bulking is of great importance in determining final yield, it seems that attempts to prolong this by inducing early initiation, as may be done in the field by early planting of an early variety, may be ineffectual because of the reduced leaf area duration—a result of lower maximum leaf area and earlier senescence—associated with this practice. Thus, early planting may not in fact prolong the duration of tuber bulking and may result in lower bulking-rates. Figs. 2 and 3 show the increase in tuber-weight for Arran Pilot and Ulster Chieftain planted on two different dates (March 22 and April 13) and it is seen that appreciable yield advantage for early planting is short-lived, particularly in Arran Pilot. Planting before mid-April is, therefore, unlikely to increase yield unless early lifting is intended.

BIOCHEMICAL CHANGES IN LETHAL STAPHYLOCOCCAL INFECTIONS IN MICE

By GEORGE W. COUNTS, Dr. IAN M. SMITH, Dr. JOSEPH I. ROUTH, Dr. ELIA Ch. HAZARD and J. F. McTAVISH

Departments of Medicine and Biochemistry, University Hospitals and State University of Iowa, Iowa City

QUESTIONS regarding the specific cause of death in staplylococcal infections remain unanswered. *Staphylococci* are known to excrete a variety of toxic substances; but it is still uncertain that these are the major factors causing death. It has also been suggested[1] that endotoxins may be important and their effects could include: (1) direct toxic action on a process essential to life; (2) indirect action by the combination of a staphylococcal toxin with a normal body component to form a lethal compound; (3)

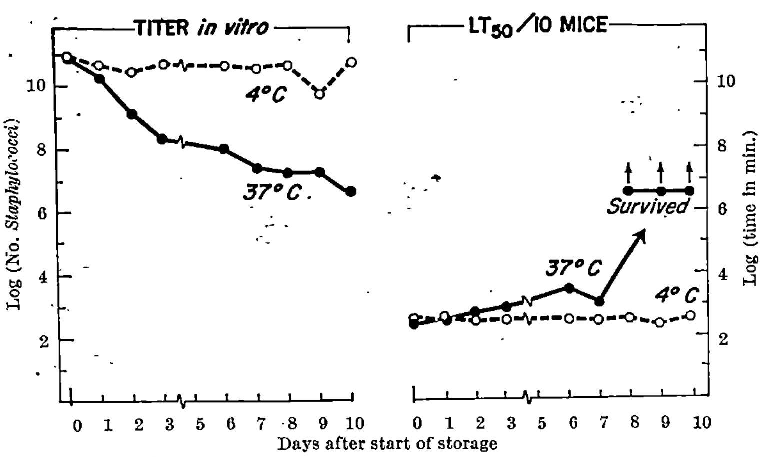

Fig. 1. Storage of staphylococcal culture at different temperatures

indirect action on the anabolism of a product essential to life and subsequent death due to deprivation; (4) the release, chemical cleavage or unmasking of a normal body component which, in excessive quantity, is toxic to metabolism.

The search for answers to this problem led to the following observations of the biochemical changes occurring in the blood of mice during a lethal staphylococcal infection.

We used the hæmolytic, coagulase-positive Smith strain of *Staphylococcus aureus*. This strain, originally phage-type *44A/42E* (ref. 2), was isolated from a patient with osteomyelitis. Using the standard phage(s) it is, however, now non-typable. It has been maintained in our laboratory by regular *in vitro* transfer. Our investigations have shown a reasonably constant number of *Staphylococci* in the bodies of moribund mice regardless of the inoculation route. Therefore, this work was confined to the use of heavy-dose (0·1 c.c. = 10^9 organisms) intraperitoneal infections. The methods have been described previously[1]. The mice used were Carworth Farms (New City, New York) White Swiss males. The animals weighed 15–18 gm. and were fasted for 12 hr. before use.

Blood was collected from the mice by beheading with scissors. Within 1 hr. after collection both serum and heparinized blood samples were transferred to the biochemistry laboratories, where blood values were established.

The values 'at death' are the result of injections of 10^9 organisms into groups of ten mice. When two of the ten animals died the remaining eight were beheaded. This was felt to be a true value since it was found earlier that, with this inoculum and this route, the animals died in 4–5 hr., and all 10 animals usually died within a span of 20–45 min.

In previous work with this strain, a particular inoculum of *Staphylococci* had to contain > 10^5 viable organisms to be lethal. In the new experiments equal parts of a culture with high numbers of organisms were allowed to age at 37° C. and 4° C. Aliquots of these two samples were tested daily for their potency *in vitro* and *in vivo*. With the culture stored at 4° C., there was little change in the titre of the culture during the period of observation, and also little change in the time required for a standard injection of this culture to kill a group of mice. With the 37° C. culture there was a direct correlation between the decreasing titre *in vitro* and the gradually declining ability to kill mice (Fig. 1).

Biochemical values for normal and infected *CFW* mice are given in Table 1. A comparison of the values in the normal and intraperitoneally infected mice showed statistically significant differences in these four values ($P \leqq 0·05$); increased transaminase, alkaline phosphatase, and inorganic phosphorus and decreased sodium. There may be important changes in the cholesterol and serum carbon dioxide values, but results so far have not been significant. Abnormal biochemical values of the same order were obtained following infection by several other routes (Table 2).

To follow the trend of these biochemical changes, blood samples were collected at hourly intervals following infection and subjected to analysis. Fig. 2 shows the large increase in alkaline phosphatase and inorganic phosphorus during a 4–5-hr. infection. While there was no significant difference between normal and terminal values for fasting blood sugar, there was a distinct hypoglycæmia occurring between the first and second hours. However, due to homeostatic mechanisms, the sugar values at death were within our established normal limits for the mouse.

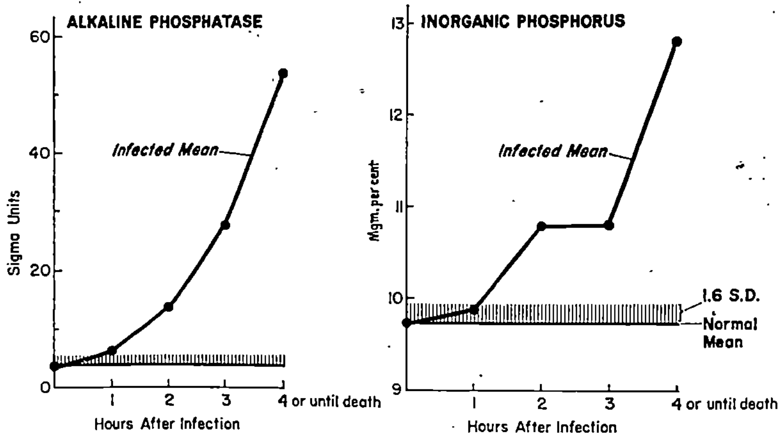

Fig. 2. Biochemistry of murine staphylococcal infections

The intraperitoneal injection of 10^{10} heat-killed *Staphylococci* produced early transient signs of illness, but no deaths, in the 14-day observation period. Blood samples collected at intervals of 8, 12, 24, 36 and 48 hr. and after 5 days showed no biochemical changes similar to those occurring during a lethal infection (also Table 2).

A strain of *S. albus* (*S. epidermidis* – coagulase-negative) obtained from a patient with septicæmia (case 6, ref. 3), although innocuous to mice in normal doses, was lethal after an inoculum of 10^{10} cells intraperitoneally. Blood values present at death failed to show the biochemical abnormalities produced by *S. aureus*. This was true with three other *S. albus* strains from patients with septicæmia.

Attempts to obtain a filtrable lethal factor from cultures of staphylococcal broth were unsuccessful. Intraperitoneal injections of 1·0 c.c. of sterile filtrate, obtained at various stages in the growth of the organism in brain–heart infusion broth were innocuous. Injections of 1·0 c.c. of sterile filtrate produced no deaths or obvious signs of illness in the animals, although it is possible that some toxic material was absorbed by the filter pad.

In addition, no filtrable lethal factor could be obtained from the serum of moribund animals when 0·5–2·0 c.c. were injected intraperitoneally into healthy recipient mice.

The results indicate that at the time of death from virulent *Staphylococci* in mice there is a high concentration of transaminase, alkaline phosphatase and inorganic phosphorus and a low sodium. A transient fall is noted in the blood glucose. These changes in the internal *milieu* are dependent on a heat-labile substance in the bacterial body. Blood serum with these biochemical changes, however, is not lethal intraperitoneally in an amount equal to an animal's circulating blood volume. *S. albus* does not produce these biochemical changes.

Various observations of changes in blood sugar, glycogen and phosphorus values occurring in experimental infections have been reported. Zeckwer and Goodell[4] studied anaphylaxis from killed bacteria injected into rabbits, and postulated that the hyperglycæmia present at death was the result of increased glycogenolysis rather than an interference with glucose metabolism. Injecting killed bacteria into rabbits, Delafield[5] showed that Gram-positive and Gram-negative organisms elicited different responses. Gram-negative bacteria caused an initial hyperglycæmia followed by a low content of sugar in the blood at 24 hr., and at the same time there were increased inorganic phosphorus values. Gram-positive bacteria, on the other hand, caused no significant changes in blood sugar or inorganic phosphorus. Kun and Miller[6], using *Salmonella* endotoxin in rabbits, reported essentially the same result, and in addition showed significantly reduced glycogen content of liver and muscle tissue. Similar blood sugar results were reported recently[7] following injections of anthrax toxin into rabbits. The hyperglycæmia was correlated with a decreased content of liver glycogen. A marked increase was also observed in the activity of alkaline phosphatase and transaminase.

An apyrase (adenylpyrophosphatase) can be extracted from several bacteria, but *Staphylococcus aureus* excretes apyrase into the culture media[8]. This enzyme liberated inorganic phosphorus from adenosine triphosphate, adenosine diphosphate, adenosine monophosphate and diphosphopyridine nucleotide. This work should be extended to *in vivo* tests.

We are studying at present the effects of accentuating or neutralizing these biochemical derangements in an attempt to devise a biochemical treatment for staphylococcal infections in the mouse[9]. This should

ELECTRON MICROSCOPE OBSERVATIONS OF THE RECEPTORS IN THE SENSORY VESICLE OF THE ASCIDIAN TADPOLE

By NOËL DILLY
Department of Anatomy, University College, London

THE free-swimming larvæ of sea squirts react to light and gravity in a manner that ensures their wide dispersal. The receptors sensitive to these stimuli are situated within the cerebral vesicle of the tadpole. In the species examined these consist of a unicellular otolith, and an ocellus made up from about ten cells. Since there are only about 60 cells in the whole of the cerebral vesicle the connectivity patterns of these receptors might yield important clues as to the manner in which they influence the motor systems of the tadpole.

Tadpole larvæ of *Ciona intestinalis, Phallusia mammillata* and *Ascidia nigra* were fixed in buffered osmic acid or potassium permanganate and embedded in 'Araldite'. Some specimens were stained in 1 per cent phosphotungstic acid in absolute acetone before embedding. The material was examined in a Siemens Elmiskop electron microscope.

The Otolith. This gravity receptor protrudes into the cavity of the vesicle from a small group of cells, which form a mound on the ventral wall (Fig. 1). The otolith itself is a single cell, consisting of an intracellular dense black mass of material, a narrow stalk, and an L-shaped 'foot'. The foot is situated in the group of cells forming the mound, whereas the narrow neck and dense body project into the cavity of the vesicle. This body is dense in the sense that it is opaque to light and electrons as well as being heavy. It is a sphere 15μ–25μ in diameter, and since its density is greater than that of the other cell contents it probably acts as the weight that distorts the otolith cell during rotation of the tadpole. The fact that it is densely black and is situated near the ocellus suggests that perhaps it may also function as a shutter, cutting off light from the ocellus intermittently as the otolith moves during rotation of the tadpole.

The remaining part of the otolith cell, which is free within the cavity of the cerebral vesicle, is conical in shape and contains the nucleus. The junction between fixed and free portions of the otolith cell is organized in a complex manner. The cell membrane is folded back on itself to form a collar around the stalk of the cell in such a way that the collar makes a socket around the stalk. The organization of this collar is further complicated because the cytoplasm is filled with distended vesicles of the endoplasmic reticulum. The collar is roughly cylindrical in outside shape, whereas the inner surface slopes inwards conically from a wide base above, to a narrow neck below. The stalk at the junction is only about 0·75μ in diameter. It seems remarkably thin to support the mass of the otolith. This is obviously the junction where maximum distortion will occur as the otolith moves in the cerebral vesicle and must therefore be suspected as the transducer region.

The foot region of the otolith cell, that is, the fixed region, extends at right angles to the long axis of the remainder of the cell, to give the whole structure an L shape. The right angle of the L is occupied by a further cell, which is probably a neurone. This cell differs from the other cells in the mound in that it is

oval in shape and has a long cell process, which is probably an axon running initially transversely across the cerebral vesicle. The oval shape of this cell is such that the short arm of the L is pyramidal in shape whereas the long arm is narrow in the middle and wide at each end. The constant position and presence of this cell in the angle of the L, together with its process, suggest that it is probably the neurone that transmits the impulses generated by movements of the otolith. This may be effected by generator potentials in the junctional region causing action potentials to be generated in the neurone; or the neurone may be distorted mechanically by movements of the otolith.

Both sides of the vertical pyramidal region of the foot are attached to their surrounding cells by specializations of the cell membranes similar to the attachment plaques described by Odland[1], and probably serving to anchor the foot firmly to the surrounding cells.

There is a set of fibrils in the otolith running from the membrane folds of the fixed free junction through the cytoplasm of the foot region to the basement membrane. They arise from the narrowest innermost part of the neck region and are attached to the innermost membrane of the basement membrane. They are 150–250 Å. in diameter and perhaps serve as a mechanical anchor for the neck region so that it cannot be excessively distorted.

The Ocellus. The ocellus (Fig. 2), the photoreceptor, is made up of three parts, a pigment cup, a lens system and a retina. It is situated at the caudal end of the cerebral vesicle.

The pigment cup situated between the lens and the retinal cells is a single cell with the lens cell contained partly within its concavity. It contains a mass of pigment granules, varying in diameter between 0·5 and 2μ and probably all bound by a membrane. The granules are more concentrated in the thick central region than at the periphery of the cell. The nucleus is confined to the non-granular apex of the cell. The function of the pigment cell is obviously to keep stray light from falling on the photoreceptor endings, thus ensuring that only light that has been orientated by the lens falls on them.

The lens system is usually unicellular, but may consist of two or more cells. There are usually three lens vesicles, arranged in a line along the main axis of the concavity of the pigment cup. The lens vesicles vary in diameter between 6μ and 12μ. They are usually spherical in shape. Each vesicle is separated from the rest of the cytoplasm of the lens cell by a single-layered sphere of mitochondria. There is no membrane separating the lens vesicle contents from the rest of the cytoplasm of the lens cell. There are no cell organelles within the vesicles, which are filled with a granular material similar in composition to the background granular material of the extravesicular cytoplasm, but in a less-dense concentration. These granules, 150–200 Å. in diameter, are usually distributed homogeneously throughout the vesicle; however, occasionally they have a greater concentration at the centre of the vesicle than at the periphery. The nucleus of the lens cell is usually in that part of the cell distal from the pigment cup.

The retina consists of about eight cells arranged in a row outside the dorsal arm of the pigment cup. They are conical cells, resting on the basement membrane that separates the cerebral vesicle from the rest of the body. These cells narrow distally to form tubes that penetrate the pigment cup and end as piles of membranes closely applied to the lens cell in the base of the concavity of the pigment cup. The retinal cells can thus be considered to have three parts: the main cellular part outside the pigment cup, the tubular part, which penetrates the pigment-containing cell, and the piled membrane photoreceptor part.

The main cellular part is of a truncated cone shape, narrowing from a wide base resting on the basement membrane down to a narrow neck at the outer edge of the pigment cell. This part of the retinal cell contains the nucleus. As yet no synapse-bearing foot process has been found.

The single tubular part of each cell penetrates the pigment cell and is cylindrical, about 6μ long and 0·75μ in diameter. It extends from the apex of the retinal cell body to the piled membrane photoreceptor part of the cell. The tube contains numerous (50–100) filaments running along its long axis. These filaments are solid, some 150 Å. in diameter and without cross striations. They do not run parallel to one another but are tangled together along the length of the tube. These filaments do not penetrate into the retinal cell body cytoplasm. The retinal cell tubular part is separated from the cytoplasm of the pigment cup by its own cell membrane, and the cell membrane of the pigment cell. Along the lengths of these two membranes are membrane thickenings similar to attachment plaques. This tubular part probably corresponds to the connecting cilium described by De Robertis[2] in the retinal rods of the rabbit. It is unlike it in that in transverse section it does not contain tubules in the normal organization of the cilium (that is, nine peripheral and two central).

At their central ends each tube is continuous with a piled photoreceptor membrane. This corresponds well with the usual vertebrate rod pattern, consisting of piles of membranes arranged in disks 150–200 Å. thick and up to 2·5μ in diameter. The piles are several μ long and are arranged perpendicular to the direction of the light falling on them.

Thus the main morphological feature of vertebrate photoreceptors, a layered lamellar structure, is present in the sea-squirt tadpole.

I wish to thank Prof. J. Z. Young and Drs. E. G. Gray and J. D. Robertson for advice and criticism.

LIMITATIONS OF GEOMETRICAL MODELS FOR COMPLEMENTATION MAPPING OF ALLELIC SERIES

By Prof. ELOF AXEL CARLSON
Department of Zoology, University of California, Los Angeles

THE first attempt to construct a gene map from the functional relations between alleles was carried out in the scute series of *Drosophila melanogaster*[1-3]. This system of 'step-allelism' assumed, by analogy with 'deletion mapping', that the complementary relations expressed in the progeny derived from various allelic crosses represented spatially distinct sub-genes or regions of the scute gene. It was, however, based on the further assumption that each sub-gene controlled one specific character—in this case, a characteristic set of bristles. This latter assumption turned out to be erroneous because the map relations were no longer maintained in the same linear order when temperature differences[4] or genetic modifiers[5] were used in conjunction with the allelic crosses. Furthermore, a radiation breakage analysis[6] of this small region indicated discontinuous organization of the genetic units with many fewer elements than proposed in the step-allele analysis. Nevertheless, at least two separable elements (achæte and scute) were definitely established[7].

In recent years a similar use of functionally complementary relations among alleles has been made, and the process has been called complementation mapping[8,15]. In some systems the complementation units inferred from the phenotypically non-mutant heterozygotes are unambiguously distinct, spatially, as judged by recombination, as well as functionally. These systems require all the point mutations in one complementation unit to complement all the point mutations in the other complementation unit. Such a relation has been typically designated as non-allelism. In other cases, there are additional point mutations, not known to involve deficiencies or other re-arrangements of the genetic material, which cannot complement at all. Such mutants appear to extend their genetic effect to all the complementation units in an allelic series. This is the more typical expectation of complementation studies for allelic series, and it has been referred to as intralocus complementation. Further use of this technique has produced complementation maps involving four, six, or more complementation units (Table 2). In all these cases one or more complementation units may be affected by a point mutation. This expression of effect by the mutant is known as its complementation pattern.

In evaluating these complementation maps, several assumptions and variables must be explored. One requirement is a knowledge of the number of complementation patterns which are consistent with linearity. A second factor would be the number of other possible geometrical models which could satisfy a complementation mapping procedure. A third important problem is whether the maps derived from complementation studies are co-linear with those derived by recombination analysis (either by the use of associated outside marker genes or by use of matrices ordered for a topological correspondence to linearity[9]). Each of these criteria involves difficult genetic problems which defy a simple analysis. For example, it is now widely recognized that almost all allelic series (especially in micro-organisms) are bound to yield recombination among most of the members tested if large enough numbers of progeny are scored[10]. This might create a misleading sense of confidence in the correspondence of a complementation map to the spatial separability demonstrated by recombination. Although the complementation test often assumes and predicts spatial separability, it must be kept in mind that allelism *per se*, in present-day genetic thinking, also assumes the likelihood of a separability, by recombination, of the mutationally altered sites in different alleles. Another difficulty not always appreciated is the non-randomness of the mutations occurring within a genetic region[11]. The resulting mutational spectrum for a given gene may be interpreted to have arisen as a consequence of hot spots, varying length of the genetic sub-units, or the sensitivity of certain regions to mutational damage because their alterations involve a region critical to the specification of the active functional region of the gene product. Other areas of the gene, altered with the same frequency, may produce fewer mutations because the final product of the gene is not altered in a region critical to its function. Such apparent intragenic mutational differences may lead to inaccurate interpretations of the number of complementation units in an allelic series.

Mathematically, the relations between the complementation units and the complementation patterns possible for allelic series are summarized in Table 1. These show that a linear map involves only a portion of the patterns possible in abstract terms, especially as the number of complementation units increases. Two other maps are possible by use of this process—circular and conical models. The special geometrical cases, such as triangularity for three complementation units, the tetrahedron for four units, and pyramids with polygonal bases for larger numbers of units, all have properties topologically identical to either the circular or conical models mentioned. Notice that if four or more complementation units are proposed for a gene, all its complementation patterns can be satisfied by the conical model. If only one or two complementation units are proposed, both linearity

Table 1. Relation between Complementation Units, Patterns and Maps

Complementation units proposed	Maximum patterns for linearity	Maximum patterns for circularity*	Maximum patterns possible†

n	$n\left(\frac{n+1}{2}\right)$	$n(n-1)+1$	2^n-1

* Without radii.

† For four or more complementation units the maximum pattern can be achieved by a cone with (n) faces or a circle with n radii.

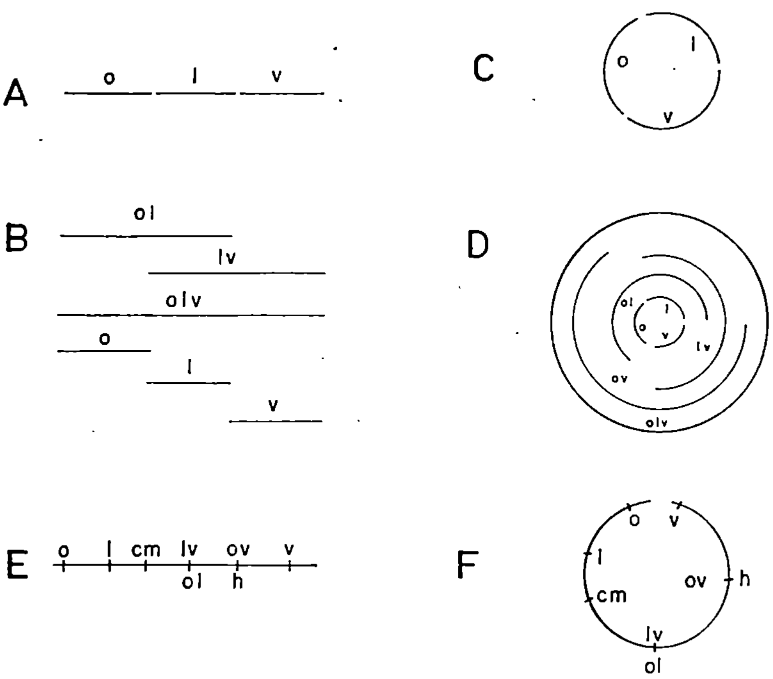

Fig. 1. *o*, Oblique wings; *l*, lethality; *v*, thoracic vortices; *cm*, comma, a weakly expressed mutant with *o* and *v* effects; *h*, humpy-like, an allele with exaggerated *o* and *v* effects. *A*, the linear complementation map with three complementation units. *B*, the six complementation patterns consistent for linearity. In this sequence, *o–l–v*, the omitted member is *ov*. If the sequence were *l–o–v*, the omitted member would be *lv*; for *o–v–l*, the omitted member would be *ol*. *C*, the circular complementation map with three complementation units. *D*, the seven complementation patterns consistent for circularity. *E*, the recombination map—all sites recombine with the other neighbouring sites and order is determined by positions of outside marker genes in the recombinants. *F*, the recombination map, if visualized as a circular map for correspondence with complementation map *D*. Note the discontinuities in *o* and *l* effects in both map *E* and *F*

and circularity can be satisfied. It is, of course, unlikely that these non-linear maps have any physical correspondence to gene structure.

An example of non-linearity in complementation mapping can be found in the dumpy series in *D. melanogaster*[12]. Here the three effects which are expressed by either the wing (*o*), thorax (*v*) or viability (*l*) produce a maximum of $2^n - 1 = 7$ complementation patterns. A linear map can be satisfied if $n\left(\frac{n+1}{2}\right) = 6$ patterns are obtained. However, the known phenotypes of the point mutations in the dumpy series suggest seven patterns: *o*, *l*, *v*, *ol*, *lv*, *ov*, and *olv*. This would correspond to a circular complementation map, since $n(n - 1) + 1 = 7$. Essentially similar arguments were proposed earlier to reject an interpretation of this series as a nest of three closely linked genes[13]. Notice that when the various complementation maps are compared with the directly determined recombination map, there is no obvious relation (Fig. 1).

It is, of course, possible that developmental complexities in *Drosophila* make allelic complementation an analogous, unrelated process to that found in viruses, bacteria and fungi. Nevertheless, all the intensively studied allelic series in micro-organisms must meet certain requirements for a critical demonstration of a spatially linear complementation map of the gene. These are, first, that the maximum permissible number of complementation patterns for the set of complementation units has been achieved and not exceeded. Because of the non-randomness of the allelic series collected, there is no easy way to eliminate the possibility of complementation patterns greater than $n\left(\frac{n+1}{2}\right)$, but certainly several alleles should be assigned to each of the complementation patterns. Secondly, the map obtained by the complementation technique, if it is intended to reflect gene structure, should be co-linear with the recombination map[14]. To date, this has not been achieved in a clear-cut way since, as examination of Table 2 indicates, the necessary maximum has not been achieved or the status of linearity is not an exclusive one. In the absence of these rigid criteria, it may be misleading to state that two genes or alleles are separated by a distance of several complementation units. It is entirely possible that the complementation units may have no real physical significance[15] for gene structure, and thus their maintenance for complementation mapping would require such *ad hoc* hypotheses as spreading effects[16], polymerization of gene products[17], or cytoplasmic recombination at the protein or ribonucleic acid template-level[8]. Additionally, it must be borne in mind that not all complementation patterns may exist in an allelic series; that co-linearity may exist for only certain portions

Table 2. Status of Complementation Mapping in Various Loci

of complementation and recombination maps; and that complementation may exist for two alleles which, by recombination analysis, are shown to occupy the same site.

Although it is not possible either to confirm or to invalidate the linearity of complementation mapping, the phenomenon of complementation is a real one and its value for understanding gene function, and indirectly, gene structure, is not denied[18]. Nor does the limitation imposed by the concept of the complementation unit rule out the cytoplasmic reassociation of component polypeptides of an enzyme or other protein[19,20]. Such demonstrated mechanisms of cytoplasmic complementation may be independent of the structural assumptions inherent in the complementation mapping of the particular gene involved. It seems, however, that the alterations in the gene molecule and the functional disturbances produced in its final product are more complex than can be accounted for on the assumption of mere co-linearity between genetic recombination and genetic complementation.

This work has been supported by grant *G*14222 from the U.S. National Science Foundation. I also wish to thank Drs. H. J. Muller and D. G. Catcheside for their criticisms of this manuscript.

RELATIONSHIP BETWEEN SIMPLE AND SERIAL REACTION TIMES

By PROF. H. KAY and DR. A. D. WEISS*

Department of Psychology, University of Sheffield

IT is one of the oldest findings in experimental psychology that when a subject has to respond to a discrete signal some measurable delay will occur. But this delay is due to many variables which are not yet fully understood. Where a response is required to a second stimulus, closely following a first, the second reaction time (RT_2) has generally been shown to be much longer than the simple reaction time, so much so that a different kind of explanation has been proposed for the so-called 'psychological refractory phase'. It was the underlying hypothesis of these experiments that work on serial reaction times may have been handicapped by stemming primarily from Telford's[1] work and by ignoring the variations which occur in the simple reaction time itself. Delays in responding in the serial situation have been treated as if they were unique[2], but may in fact closely parallel fluctuations in the simple reaction time. This article reports some of the findings of an investigation designed to make an overall comparison of simple and serial reaction times.

Subjects sat in a sound-treated room wearing padded ear-phones and responded to an auditory signal by releasing a morse key. The design of the experiments, unfortunately complicated, manipulated fixed and variable intervals before both the first and second signals. Table 1 sets out these conditions. After a subject had pressed a 'ready' key there was a warning delay of either 1, 2, 3, or 4 sec. In the regular condition it was known which of these intervals would be used ; in the irregular it might be any one of the four periods. The first click occurred at the end of the warning delay and was followed by a fore-period terminated by a second click. There were eight fore-periods ranging from 25 to 1,000 m.sec. and again these might be regular (a known interval) or irregular (any one of the eight). Catch trials were used with all regular procedures.

Data were taken from five practised subjects. In all some 20,000 readings were recorded, excluding practice data, and, with the use of an electronic computor, were examined by analysis of variance. Any differences which are discussed were statistically significant.

At procedures I and II simple reaction times were examined after regular and irregular warning delays. The mean *RT*'s with the regular warning delay at the 1-, 2-, 3- and 4-sec. intervals were 134·3, 146·6, 146·3 and 152·6 m.sec., respectively. At the same intervals for the irregular procedure these means were 164·4, 146·4, 146·6 and 146·5, respectively. The 1-sec. warning delay produced the quickest response in the regular procedure and the slowest in the irregular.

To facilitate comparisons for the remaining procedures the results for all the fore-periods based on a mean of the four warning delays are presented in Table 1 and have been graphed in Fig. 1. The striking feature of the graph is the manner in which reaction time increases at the minimum fore-period with the increasing ambiguity of the experimental conditions. With procedure III, where both warning delay and fore-period were regular, the reaction time was almost the same for the fore-periods from 25

Table 1

Procedure No.	Warning delay	Fore-period	Signal responded to	Fore-periods (m.sec.)							
				1 25	2 50	3 100	4 150	5 200	6 250	7 500	8 1.000
III	*R*	*R*	2	155	158	152	153	161	150	126	125
IV	*R*	*I*	2	175	166	154	155	156	159	147	131
V	*I*	*R*	2	189	176	159	154	151	144	123	115
VI	*I*	*I*	2	192	180	159	148	152	146	130	113
VII	*I*	*R*	1 and 2	244	234	199	185	173	163	126	108
VIII	*I*	*I*	1 and 2	265	246	218	195	197	180	136	119

Mean response times (m.sec.) to the second signal after a regular (*R*) or irregular (*I*) warning delay and fore-period. Warning delay intervals 1–4 sec. Fore-period, 25–1,000 msec.

Analysis of variance, using a random model as the conservative index of significance, gave *F*-ratios which were significant at the 0·01 level or above between the fore-period conditions of procedures V and VII, VI and VIII, and VII and VIII.

to 250 m.sec. For the irregular fore-period of procedure IV it increased slightly at the 25- and 50-m.sec. interval. With procedure V, where the 1–4 sec. warning delay was irregular, followed by the second click at a prescribed interval, subjects were slower in responding at the shorter fore-period than in procedure III where the warning delay preceding the first click had been regular. There was a further increase in reaction time at the shortest fore-periods for procedure VI, where both warning delay and fore-period were irregular. But it is obvious from the larger displacements for procedures VII and VIII that the delay resulting from perceiving an immediately preceding signal by no means accounts for all the interference of these responses. Procedures V and VI were identical with VII and VIII except that, in the two latter, subjects not only observed the first click but also manually responded to it. The slower reaction times which occurred to the second click as a result of this previous response were considerable and persistent. The results for procedures VII and VIII were not unlike those found by other work on the refractory phase, though the magnitude of the delay was not so great as in some earlier experiments.

If the results for procedures VII and VIII were considered in isolation, or against some so-called 'average' reaction time, it is apparent why an explanation of the 'psychological refractory phase' type would be necessary. There is a large increase as against some standard reaction time of say 140 m.sec. for an auditory stimulus. But in the present work the comparison is with reaction times produced under conditions which have varying degrees of similarity to those of the final procedures, VII and VIII. It is clear that with increasing uncertainty as to when either signal would occur there was an increasing reaction time at the shortest fore-periods. It is certainly the case that even the observation of a previous and irregular signal retarded the response to the critical signal, as in procedures V and VI. But this perception, contrary to the assertion of some workers, has been shown to be only one of many variables contributing to the delay. The manual response to the first click, in procedures VII and VIII, definitely increased further the delay in responding to the second click.

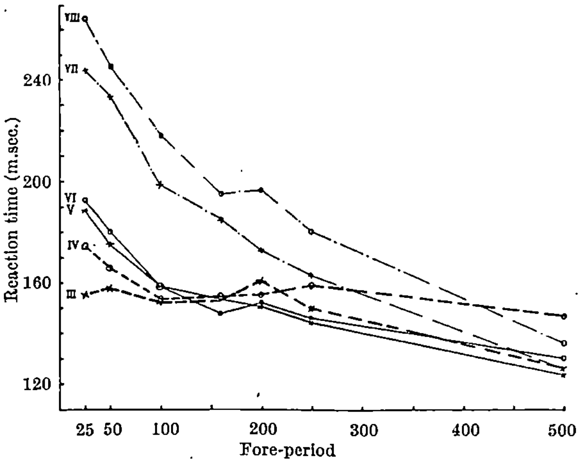

Fig. 1. Mean response times (m.sec.) to second signal at fore-periods 25–500 m.sec.

III: × – – ×, regular warning delay, regular fore-period.
IV: ○ – – ○, regular warning delay, irregular fore-period.
V: × — ×, irregular warning delay, regular fore-period.
VI: ○ — ○, irregular warning delay, irregular fore-period.
VII: × —●— ×, RT_2 irregular warning delay, regular fore-period.
VIII: ○ —●— ○, RT_2 irregular warning delay, irregular fore-period.

From this series of experiments it would seem that the variability in the simple reaction time, shown so clearly by Breitwieser[3] and Woodrow[4], is closely mirrored in the serial reaction-time situation. Theorists have been prone to postulate rigid fixed intervals of time between the completion of one response and the initiation of the next. The present work casts serious doubts on this approach. It would support previous work in so far as no two reaction times are overlapping, and there is the usual pronounced delay with the standard serial reaction-time situation of procedures VII and VIII. But this situation is only an extreme example of how RT_2 can be delayed. If we think of a minimal simple reaction time only occurring when the organism is optimally prepared to make a response to a signal, we have evidence from present and previous work how the reaction time will vary with uncertainty as to when the signal will occur. It would appear that in cases of such uncertainty the state of readiness of the organism cannot be raised to one critical peak point in time. In the case of the serial reaction time any signal which has to be perceived and which occurs immediately before the critical second signal, serves to lower the state of readiness of a subject. The disruption seems related to the degree of uncertainty of the first signal, and the extent of the response which is required. We might say that in the serial reaction-time conditions, the restriction where a subject has to observe a first signal and respond as quickly as possible to it is an optimally disturbing condition on the preparatory set for perceiving and responding to the second signal (RT_2). It would follow that one possible explanation for the delay in responding to the second signal is along lines identical with those for explaining the variability in the speed of responding to the first.

RADIOPHYSICS

Trans-Equatorial Backscatter Observations of Magnetically Controlled Ionization

A ROTATING backscatter equipment operating at Brisbane on a frequency of 16 Mc./sec. with a highly directional aerial[1] has been modified to record echoes with ranges up to 15,000 km. It is found that on 95 per cent of afternoons echoes are returned from a north-easterly direction with ranges of 6–12,000 km. Typical sequences are shown in Figs. 1 and 2, where the plot is one of range versus magnetic azimuth from Brisbane.

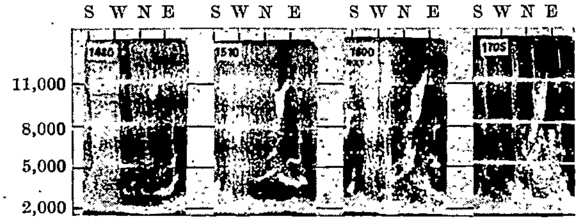

Fig. 1. Range–azimuth records of trans-equatorial backscatter. 6/10/60

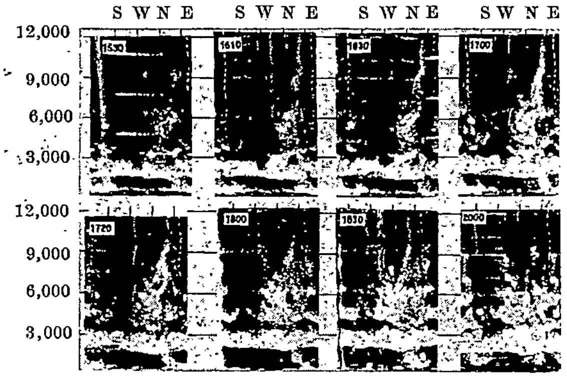

Fig. 2. Range–azimuth records of trans-equatorial backscatter. 2/1/61

It is well known that the electron density of the *F* region in the afternoon is less near the magnetic equator than in two sub-tropical belts at geomagnetic latitudes of about ± 20°, and several theories have been put forward to account for this phenomenon[2–5]. These theories involve the electrodynamic uplift of ionization at the equator and its subsequent downflow along the magnetic field lines to the sub-tropical regions near ± 20° M. In addition, Wright[6] has produced meridianal sections of the quiet day ionosphere, showing the extremely rapid variations of the ionization contours as a function of height and latitude.

If one compares the locations of the long-range echoes referred to here with the parallel of magnetic latitude 20° N. (that is, computed from the actual dip values), it is found that the echoes generally lie very close to this line. Two specific instances from the sequences of Figs. 1 and 2 are shown in Fig. 3.

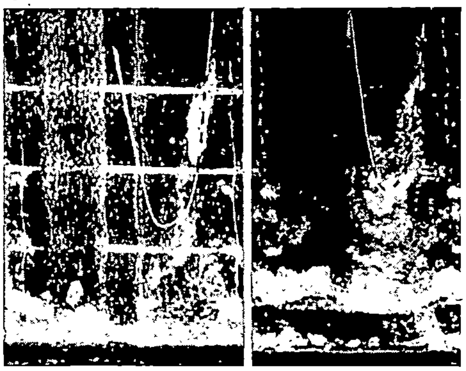

Fig. 3. Range-azimuth records for *a*, 1600/6/10/60 and *b*, 1700/2/1/61 with overlay plots of the 20° N. parallel of magnetic latitude

The question of the propagation mechanism is rather involved as the echoes come from regions in which the local time may be up to 6 hr. ahead of the local time of observation at Brisbane. It is believed, however, that the main mechanism is that of 'tilt-mode' propagation proposed by Villard *et al.*[7], sometimes with a single hop to the *F* region before the equatorial jump. This hypothesis is being examined further by computing the expected oblique profiles of ionization density at various times and in various directions from Brisbane.

The fact that the eastern limb of the echo is the predominant feature is probably due to the changing ionospheric conditions as one proceeds from east to west with changes in time of several hours. By the time the western limb should be visible at long ranges, the electron density south of the equator is too low for the necessary propagation conditions to be set up.

It appears probable that such observations of the whole length of the belt of high-density ionization are only possible with highly directive antennæ. The signal is often weak and scattered and with a broad beam antenna may well merge into the background noise. This point is to be checked shortly, and further tests will be made with a swept-frequency backscatter sounder operating at 15–30 Mc./sec. and with an additional fixed-frequency sounder operating at a higher frequency.

RADIOASTRONOMY

Central Component of the Radio Source Centaurus *A*

The identification of the radio source Centaurus *A* with the peculiar galaxy *NGC* 5128 was first suggested by Bolton, Stanley and Slee[1]. The radio source consists of an extended component with dimensions of about 2° × 4° and a compact central component. The extended source has recently been shown by Bolton and Clark[2] to consist of two components. The compact central component was investigated in 1953 by Mills[3]. His observations indicated that the radio emission was associated with the wide dust band of *NGC* 5128. Recent measurements by Twiss, Carter and Little[4] have shown that the central source also consists of two components. This result was also obtained by Moffet and Maltby[5]. In a more recent radio investigation of *NGC* 5128, reported in this communication, I find that the radio source is not associated with the wide dust band.

Using the variable spacing interferometer at the Owens Valley Radio Observatory, Centaurus *A* has been observed with different antenna spacings and in different orientations. The measurements were taken at wave-lengths of 21·6 cm. and 31·3 cm. In order to determine the position of the minor axis, the source was observed for about 2 hr. on either side of upper culmination with a north–south interferometer. At the latitude of this Observatory the source is close to the horizon, and a relatively long horizontal antenna separation is therefore needed to investigate the source in the north–south direction.

In Fig. 1 the observed fringe amplitude is plotted against hour angle for two different antenna separations. Fig. 1*a* shows the observations at 31·3 cm. using a horizontal antenna spacing of 800 ft., while the curve in Fig. 1*b* is obtained at 21·6 cm. with the antennas 1,600 ft. apart. The accuracy of the individual points in the curves is ± 3 per cent of the maximum intensity of the source. In the following, we will neglect any change in the brightness distribution between these two frequencies. Changes in the fringe amplitude in Fig. 1 are due to changes in the effective antenna separation as well as to changes in the orientation of the source in the fringe pattern. From Fig. 1 we find that one maximum occurs at an hour angle equal to 1h. 10m. in both curves. This means that the minor axis is in a position angle of about 135°. Using the maxima and the minima in Fig. 1, it was found that the major axis is in position angle 46·5° ± 2·0°. Although the position angle of the minor axis deduced by Mills[3] was 40°, his observations would not be inconsistent with the position angle of 136·5° reported here. Indeed, all Mills's[3] observations are in reasonable agreement with the interpretation given here, if we take into account the fact that the source consists of two components.

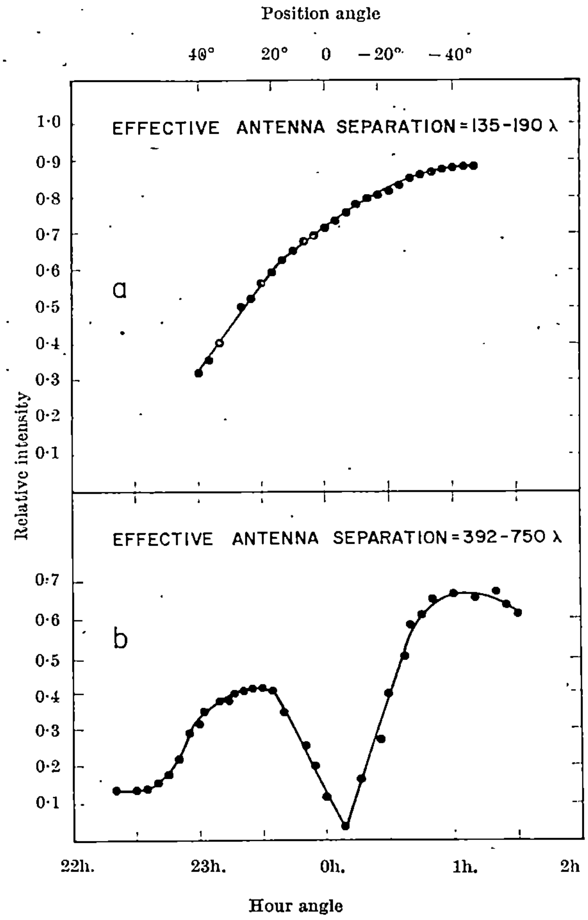

Fig. 1. Observed fringe amplitude plotted against hour angle. *a*, Observed curve at 31·3 cm. using a horizontal antenna spacing of 800 ft.; *b*, observed curve at 21·6 cm. with the antennas 1,600 ft. apart

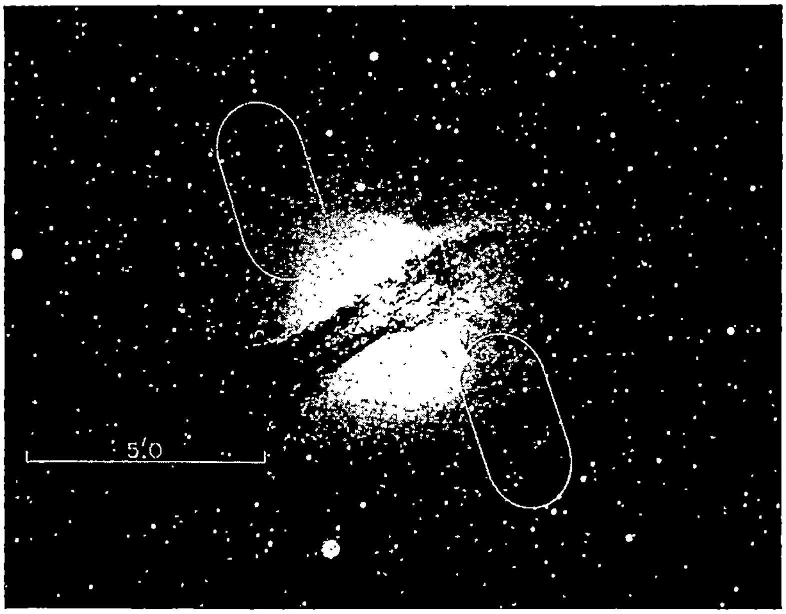

Fig. 2. Half-intensity contours of the two components in the central radio source of Centaurus *A*. The photograph of *NGC* 5128 is from the Mount Wilson and Palomar Observatories

Comparing the two maxima in Fig. 1*b*, I find that the maximum at 23h. 30m. is much lower. It may be shown that, if the source consisted of two circular components, the maximum at 23h. 30m. in Fig. 1*b* would have approximately the same value as the maximum at 1h. It is therefore reasonable to suggest that the components are elongated.

We are now in a position to derive a more detailed picture of the source. From the observations along an east–west base-line by Moffet[6], a diameter of about 2 min. of arc for each component is indicated. The curves in Fig. 1 were compared with those which would be produced by a model source consisting of two equal components 2·0′ in diameter, separated by 7·1′ along the major axis in position angle 46·5°. The elongation of the two components was found by comparing the observed and calculated curves. The interpretation was simplified by assuming that the two components have similar shapes. The shape of the components and their position is indicated in Fig. 2. A good fit to the observed curves was obtained. No significant deviation was present in Fig. 1*a*. In Fig. 1*b* the discrepancy between the calculated and the observed curve was found at the minima, where the calculated curve was equal to zero. Deviations between the curves were present between hour angles of 0 and 20m. and between 22h. 20m. and 22h. 50m. The deviation from the observed curve gave an upper limit of 1·3 to the ratio of the intensities of the components. This is in good agreement with Moffet's observations in the east–west direction[6].

From Fig. 2 it is evident that the radiation originates in a region outside the wide dust band. The major axis is approximately normal to the dust band. Each component is elongated approximately along the major axis of the extended source. It is interesting to note that the photographs of *NGC* 5128 in red light[7] show elongation of the galaxy along the same major axis as the central radio source.

It is significant to note that the sources lie on the polar axis of the galaxy. It is possible that the sources are associated with the escape of high-energy electrons from the galaxy through a polar fringing magnetic field. The non-existence of radio emission from the dust band may be explained as due to the presence of a high gas density in that region. Processes such as ionization loss will then dominate and the electrons will not lose energy by means of radio emission.

PHYSICS

Experiments on the Compression of Plasma in Cusp Geometry

CONTAINING plasma by cusp-shaped magnetic fields has for some time been considered a promising possibility because of the favourable stability properties predicted theoretically[1-4]. To investigate this configuration experimentally, an apparatus has been built in which shock pre-heated plasma is compressed by a rising cusped magnetic field.

The apparatus is shown in Fig. 1. The cylindrical 'Pyrex' discharge vessel is 20 cm. in diameter and 75 cm. long, and cone-shaped at each end to fit inside single-turn pre-heat coils. The two single-turn cusp field coils are of 22 cm. diameter with separation variable between 6 and 16 cm., and for the present experiments each coil was connected to a 600-μF. condenser bank rated at 40 kV. When charged to 24 kV., this provided an oscillating magnetic field of about 50 kilogauss at the line and point cusps, with a period of 50 μsec. The shock waves which ionize and pre-heat the initially neutral gas are produced by the simultaneous discharge of two auxiliary condenser banks into the pre-heat coils. The current in these coils rises to 200 k.amp. in a time of 1·5 μsec. Experiments have been carried out using hydrogen gas at pressures in the range 20–40 millitorr and argon and helium at somewhat lower pressures.

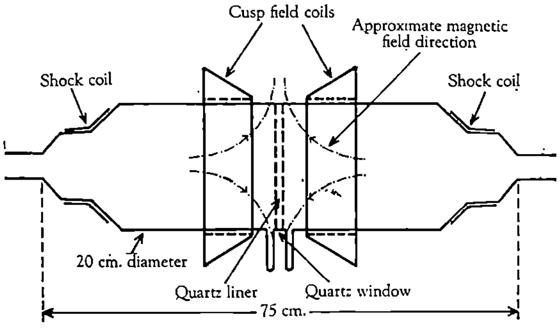

Fig. 1. Diagram of discharge vessel and associated magnetic field coils

With hydrogen at 22 millitorr, spectroscopic measurements on the bremsstrahlung and recombination continua (McWhirter, R. W. P., unpublished work) in the region of the Balmer series limit indicate that a plasma electron density of 2×10^{15} cm.$^{-3}$ and electron temperature of about 5×10^{4} °K. is produced by the shock pre-heating system.

The effect of the rising cusp field on the pre-heated plasma has been studied with a framing camera; examples of the observed phenomena are shown in Fig. 2. Fig. 2*a* shows the shocks approaching and meeting followed by the first half-cycle and part of the second half-cycle of the cusp field. Fig. 2*b* shows the growth of an instability after 2–3 μsec. in a typical case of the contraction velocity exceeding the estimated speed of sound. Fig. 2*c* shows an example of flute-type instability in helium in the very early stages of compression. Fig. 2*d* shows a condition in hydrogen in which no gross instability is observed and the full course of adiabatic compression can be seen.

It is suggested that the observed instabilities are of the Rayleigh–Taylor type[5], that is, resulting from the acceleration of the plasma by the magnetic field.

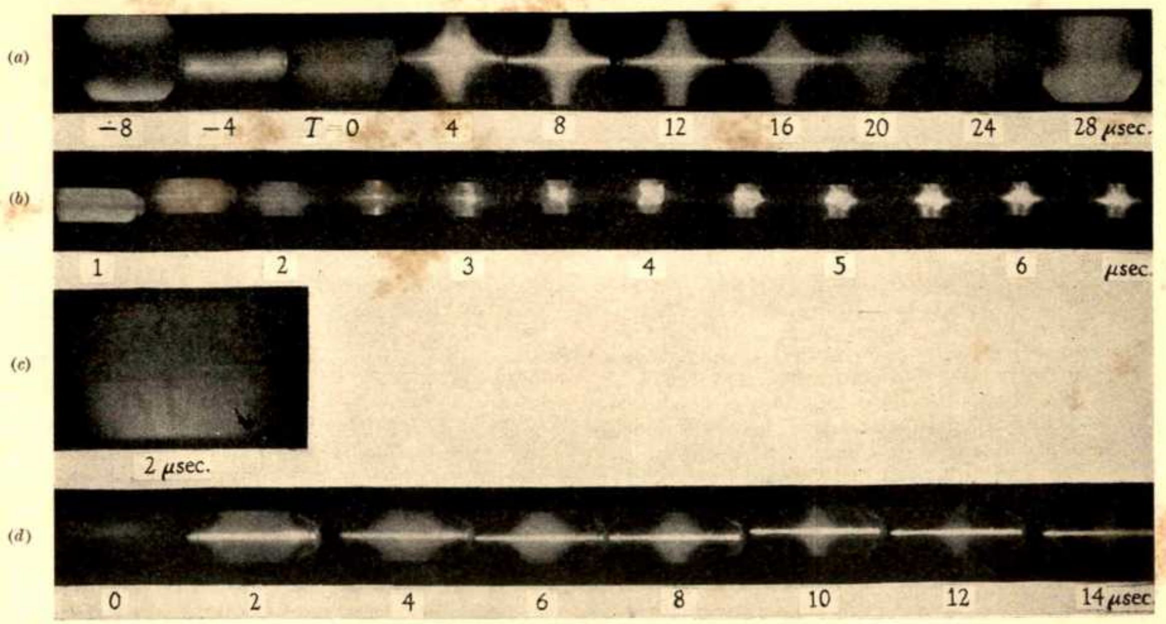

Fig. 2. Framing camera photographs of entire section of discharge tube between cusp field coils. The time at which the photographs are taken is marked. The cusp field starts rising at $T=0$. (*a*) Hydrogen–argon (5 per cent) mixture; 20 millitorr; coil separation, 16 cm.; exposure, 2 μsec. per frame. (*b*) Argon, 5 millitorr; exposure, 0·25 μsec. (*c*) Helium, 10 millitorr; exposure, 1 μsec. (*d*) Hydrogen, 35 millitorr; exposure, 1 μsec.

Such acceleration occurs during the initial stages of the compression (Fig. 2*c*) and, additionally, on the reflexion of complex strong shock patterns at the boundary in those cases where the contraction velocity exceeds the speed of sound in the pre-heated plasma (Fig. 2*b*). The criterion for stability in the relevant case of a plasma accelerated by a curved magnetic field is[1]:

$$\frac{B^2}{4\pi R} > nMf$$

where R is the radius of curvature of the magnetic field lines (taken positive for lines convex to the plasma), f is the plasma acceleration (positive for acceleration directed from the plasma towards the magnetic field), and nM is the plasma density. The observations are qualitatively consistent with this criterion in that the system is more unstable in heavier gases, and there is evidence of considerable stabilization during the later stages of compression when the sign of f changes. It should be emphasized that the instabilities discussed here are associated with the establishment of an equilibrium state, and no comprehensive results concerning the stability of such an equilibrium have been obtained in these preliminary experiments.

However, when operating conditions are such that these initial instabilities are not present, the cusp boundary appears to remain quite sharp during the first quarter-cycle. Analysis of framing camera pictures for some of the most stable and reproducible conditions, namely, 22 millitorr of hydrogen, gives volume compressions of about 15–20 after 8 μsec. Spectroscopic measurements at this time indicate an increase in density greater than 10 and an increase in electron temperature from 5×10^4 °K. to a value greater than the upper limit of 2×10^5 °K. measurable by the method.

We thank Mr. R. S. Pease for his helpful discussions, Mr. P. A. Worsnop whose engineering group built the apparatus, Dr. R. W. P. McWhirter for the spectroscopic measurements, and Mr. J. N. Burcham for much of the experimental work. The experiment profited from the initial design studies by Mr. J. G. Armstrong.

A Proposal for a Tunable Source of Radiation for the Far Infra-red using Beats between Optical Masers

In this communication, the possibility is considered of generating radiation in the far infra-red by beats between optical masers.

Oscillations from optical masers have been detected at several different wave-lengths in the region of 7000 Å. using ruby[1,2], and also calcium fluoride doped with samarium. Calcium fluoride doped with uranium ions[3] has also been used to produce oscillations at 25,000 Å. So far these solid-state optical masers have only been operated in pulses, but seem to be potentially capable of continuous wave operation.

Recently, the dependence on temperature of the oscillation wave-length of a ruby optical maser has been investigated[4] and this has been found to vary from 6934 Å. at −180° C. to 6953 Å. at 210° C. If beats between a fixed frequency and a thermally tuned optical maser could be generated, then the difference signal could be tuned from centimetre to submillimetre wave-lengths. Indeed, there is no reason why the whole of the far infra-red spectral region could not be covered by selecting the frequency of oscillation of one optical maser and thermally tuning another. The spectral purity of the actual oscillation signal is determined chiefly by crystal imperfections, and typical values of oscillation line-width lie between 0·1 Å. and 0·02 Å. Thus a possible spectral width of about 1 Gc./sec. would be expected at the beat frequency, which would be narrow enough to be used as a tunable source of radiation in the far infra-red, even with the present state of the art of optical maser construction.

In a practical arrangement, one optical maser could be operated at, say, the temperature of liquid nitrogen, and its power output mixed with the output of a second optical maser temperature controlled to a pre-set value between 25° C. and 210° C. The wave-length of the beat signal would then be continuously variable over the range of 250μ–550μ. Such a wide tuning range (which undoubtedly could be extended by a larger variation of temperature or by using crystals with a larger temperature coefficient of oscillation wave-length) is unlikely to be equalled by a single maser operating directly in the far infra-red.

As the bursts of oscillation are only 0·5 msec. in duration, fairly exact synchronism of the oscillation bursts would be required if separate optical masers were to be used. However, two optical masers would not necessarily be required to produce oscillations at different wave-lengths, since experiments with concentrated ruby[2] have shown evidence of simultaneous oscillations at 7009 Å. and 7041 Å. Beats between these two signals would give an output signal of approximately 150μ wave-length. The problem of synchronism of oscillations would not arise provided that the energy from the ultra-violet flash-lamp is greater than the threshold-level necessary to maintain both oscillations simultaneously. Such an arrangement would be rather restricted in tuning range, since both oscillation wave-lengths would be shifted by approximately equal amounts on cooling or heating the crystal. On the other hand, this may be an advantage from the point of view of frequency stability of the beat signal.

Since the pulsed output of the optical maser is typically 10 kW., any system of optical mixing must be capable of handling this power without burning out. The non-linear properties of a mercury arc[5] or a cold cathode arc[6] have been exploited for the purpose of harmonic generation of submillimetre waves from a *Q*-band klystron, and it is suggested that the power handling capacity of the arc may be well suited to mixing optical maser signals. The output from each maser could be directed on to the cathode spot quite easily as the beam diameter is typically 2 mm. It seems conceivable that several watts of pulsed power could be generated in the far infra-red even if the mixing efficiency is only a few per cent.

In contrast to the ruby optical maser, the gas discharge type[7] is not continuously tunable over a wide band; nevertheless the exceptional spectral purity of the optical oscillation (which is many orders of magnitude narrower than in the ruby device) presents exciting possibilities as a source of beat frequency in the far infra-red. The gas optical maser has been operated at five different wave-lengths in the near infra-red and the strongest signal found at 11,530 Å. with a continuous wave output of 15 mW. The spectral purity has been measured to be in the region of 10–80 kc./sec. Thus beats only a few tens of kc./sec. wide between two optical masers operating at different spot frequencies should occur at wave-lengths of 180μ and 190μ as well as at several other wave-lengths between 15μ and 37μ. The beat frequency could probably be tuned over a narrow region by a small adjustment to the separation of the interferometer plates or by a variation of the gas pressure. Mixing of the optical signals could again be carried out by using a mercury or cold cathode arc as suggested before. Some sort of focusing would be necessary in this case. In this sort of way it should be possible to produce several tens of microwatts of continuous wave-power. Even this power-level, combined with the spectral purity of perhaps only a few kilocycles, presents a very attractive approach to the long-standing problem of suitable sources for high-resolution spectroscopy in the far infra-red.

CHEMISTRY

A New Relation between the N—H Stretching Frequencies of Primary Amides

BELLAMY *et al.*[1], from the data obtained for a number of aromatic primary amines in dilute solutions, have shown that the N—H asymmetric and symmetric stretching frequencies are related by the expression $\nu_s = 345{\cdot}5 + 0{\cdot}875\ \nu_{as}$. The standard deviation of the calculated symmetric stretching frequencies from those of the recorded values is about 5 cm.$^{-1}$. These workers also mention that the same relation would not be obeyed in situations where the two N—H links are non-equivalent.

We[2,3] have recorded the N—H stretching frequencies of a number of primary amides in dilute solutions in the region of 3,530, 3,420, 3,350 and 3,200 cm.$^{-1}$ and assigned the first two absorption bands to the N—H asymmetric and symmetric stretching frequencies of the monomers and the other two to the same modes of vibration of associated molecules. Davies and Hallam[4], Davies and Evans[5], and Cleverley[6] have recorded the N—H stretching frequencies of a series of primary amides in dilute solutions. The data thus available for fourteen primary amides yield a simple linear relation between the asymmetric and symmetric stretching frequencies of the monomers recorded in the regions of 3,530 and 3,420 cm.$^{-1}$. A least-squares treatment shows that the frequencies of these two free N—H stretching vibrations are related by the expression $\nu_s = 1{\cdot}1214\ \nu_{as} - 542{\cdot}5$. In cases where the frequencies are reported by more than one group of workers, the mean values of the frequencies are used for the least-squares treatment. This relationship is obeyed for bands in the regions of 3,530 cm. and 3,420 cm.$^{-1}$, the average deviation of the calculated values from those of the recorded being about 3 cm.$^{-1}$. This relation is indicated in Fig. 1. But the same empirical relation does not hold for bonded N—H

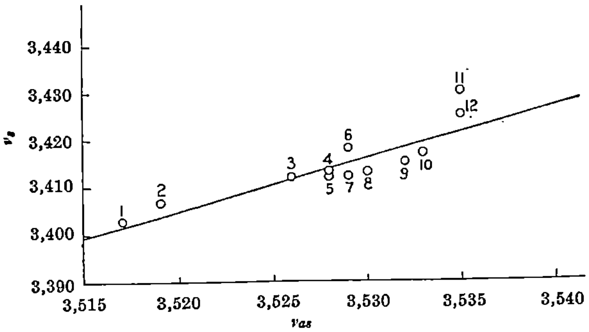

Fig. 1. 1, Trichloracetamide; 2, phenylacetamide; 3, *n*-valeramide; 4, *n*-butyramide; 5, *n*-decanamide and iso-butyramide; 6, acetamide; 7, *n*-dodecanamide and iso-valeramide; 8, *n*-octanamide; 9, *n*-heptanamide; 10, *n*-hexanamide; 11 benzamide; 12, formamide

asymmetric and symmetric stretching frequencies of the associated molecules in the region of 3,350 and 3,200 cm.$^{-1}$; the average deviation between the calculated and recorded ν_s frequencies is about 26 cm.$^{-1}$. This result is in agreement with our conclusions[3], since for the intermolecular associations proposed in our work on primary amides, it is considered that only one of the N—H links is bonded. The asymmetry thus introduced leads to the breakdown of this relationship.

The N—H stretching frequencies of four primary amides as recorded in solutions of dioxane[3] and the calculated ν_s values by the relation $\nu_s = 1{\cdot}1214\ \nu_{as} - 542{\cdot}5$ are given in Table 1.

Table 1. CALCULATED AND OBSERVED N—H STRETCHING FREQUENCIES OF PRIMARY AMIDES IN DIOXANE (CM.$^{-1}$)

Amide	N—H stretching bands		
	Observed		Calculated
	ν_{as}	ν_s	ν_s
Formamide	3,443	3,357	3,318
Acetamide	3,450	3,360	3,326
Benzamide	3,450	3,360	3,326
n-Butyramide	3,450	3,360	3,326

The smaller values for the N—H stretching frequencies of the primary amides in solutions of dioxane have been explained by us[3] on the basis that the intermolecular associations break up considerably in this solvent and the hydrogen atom of the amino group of the monomer amides form association with the donor group of dioxane. From the observations in Table 1, it is seen that the relationship proposed by us breaks down for the N—H stretching frequencies of the primary amides in dioxane. The difference between the calculated and observed ν_s frequencies is about 35 cm.$^{-1}$. This result indicates that it may not be sterically possible for two molecules of dioxane to bond to the same amino group of the monomer amides. Similar results were obtained by Bellamy and others[1] in their work on amines in solutions of dioxane.

Application of the Nickel Reaction and Thermal Isomerization of Alpha-Keto-Acid Hydrazones for their Chromatographic Analysis

THE nickel reaction, discovered by Katsuki *et al.*[1], produces a red colour with pure *cis* isomers of α-keto-acid-2,4-dinitrophenylhydrazones and differentiates them from their corresponding *trans* isomers. We have found that this reaction applies to isomeric differentiation of the keto-acid hydrazones on paper chromatograms by the following procedures:

After chromatography of the pyruvic acid hydrazones in the dark on Whatman No. 1 filter paper, using tertiary amyl alcohol/ethanol/water 5 : 1 : 4 as the solvent, the chromatogram was sprayed first with a 5 per cent (w/v) solution of nickel chloride in 70 per cent aqueous ethanol followed by a fresh 0·3 per cent suspension of zinc powder in aqueous ethanol. The paper was heated at 100° C. for a few minutes and the higher spot of the *cis* isomer turned reddish, whereas the lower *trans* spot did not. The *cis* spots of glyoxylic, phenylglyoxylic, phenylpyruvic and *p*-hydroxyphenylpyruvic acid-2,4-dinitrophenylhydrazones gave similar responses. Concentration of nickel chloride and zinc powder in alcohol and the time of heating may have to be changed depending on the intensity of chromatographic spots and the stability of the hydrazone isomers. As a matter of fact, even *trans* spots give colour responses for this reaction, if they are readily isomerized by heat. If the *cis* hydrazone of pyruvic acid is dissolved in ethyl acetate and dried on the paper, it will give an orange colour, after spraying with alcoholic nickel chloride without application of zinc powder. This does not occur if alcohol is used as the solvent, and the *trans* isomer gives no colour with either solvent.

A second useful method in distinguishing isomers involves thermal isomerization to the stable isomer. For example, a crude hydrazone from the products of anaerobic glycolysis of the sarcoma 37 solid tumour homogenates upon chromatography gave two spots for the *cis* and the *trans* isomers of pyruvic acid hydrazone respectively. However, if the crude hydrazone were heated at 120° C. for 15 min. before chromatography, only the *trans* isomer was observed, owing to thermal isomerization. Thus, it was clear that both original spots were due to pyruvic acid alone and not to two keto-acids. This identification could be confirmed by the use of the nickel reagents which coloured one of the spots in the original chromatogram and left the single spot of the second chromatogram uncoloured.

Knowledge of thermal decarboxylation of dinitrophenylhydrazones of certain β-keto-acids as well as of thermal isomerization may be combined with the nickel reaction advantageously for greater certainty. For example, from mouse urine isomeric spots for pyruvic and phenylpyruvic acid hydrazones were readily identified by such a combination. Possible misassignment of spots of pyruvic acid hydrazone as being due to acetoacetic acid hydrazone, which has an R_F close to that of pyruvic acid hydrazone isomers, was avoided, since heating the crude hydrazone before chromatography produced only a spot for *trans* pyruvic acid and none for acetone hydrazone which would have been formed from acetoacetic by thermal decarboxylation[2]. Similarly, confusion between the hydrazone of oxaloacetic acid which decarboxylates to pyruvic acid on heating, and of α-ketoglutaric acid, which does not decarboxylate, may be avoided. It should be noted that heating causes many aromatic keto-acid hydrazones to isomerize from *trans* to *cis*, the latter being the stable isomer in these cases, whereas the reverse behaviour is found with many aliphatic keto-acid hydrazones. The characterization of several aromatic keto-acid hydrazones will be presented elsewhere.

This investigation was aided by grant *C*-4342 from the National Cancer Institute, U.S. Public Health Service.

A Molecular Beam Reactor for examining the Rate, and Primary Products, of Reactive Bimolecular Collisions

A MOLECULAR beam technique has been developed which permits investigation of the primary products of reactive collisions between gas molecules or radicals. The principle of the technique can be described by reference to the schematic diagram in Fig. 1. A molecular beam of one gas, *A*, is formed at an aperture, 1, in the wall of the vessel, 2, and collimated by a second aperture, 3. The emergent beam from 3 crosses the reaction zone, 4, and leaves by a third aperture, 5, to enter a detector, 6. The latter may conveniently be a mass-spectrometer, so orientated that the molecular beam of *A* crosses the ionization chamber of the mass-spectrometer without impinging on the electrodes. With sufficient pumping speed for the collimating, reaction and mass-spectrometer compartments, the mass-spectrum peaks due to *A* are produced almost entirely from molecules which have experienced a collision-free transit from aperture 1 to the ionization region, and the contribution from 'background gas' molecules of *A* in these compartments can be made negligibly small. The second gas, *B*, is admitted into the reaction compartment at a pressure such that the mean free-path of *B* in *B* in the main body of this compartment is of the order of the molecular beam path-length in this compartment. Now let n_B be the average number of molecules of *B* crossing unit area within this compartment in unit time, and let n_A be the average number of molecules of *A* which cross unit area normal to the molecular beam path, in unit time, in the reaction zone. Two limiting cases are conceivable. If $n_A \ll n_B$, then molecules of *B* will effuse according to the cosine distribution law into the mass-spectrometer compartment. Thus the *B* molecules detected there will have arrived there as a result of collisions with other *B* molecules in the reaction zone. On the other hand, if $n_A \gg n_B$ then any molecule of *B* in the reaction zone has a much greater probability of collision with a molecule of *A* than with another molecule of *B*. Thus each *B* molecule detected in the mass-spectrometer will have arrived there by a collision-free path from a collision with an *A* molecule in the reaction zone. As a first approximation the rate at which such molecules reach the detector is the same as for the case of molecular effusion in the absence of the beam of *A* molecules. If, therefore, *A* and *B* are molecular species which react together, it is possible to detect the primary products of the reactive collisions in the reaction zone.

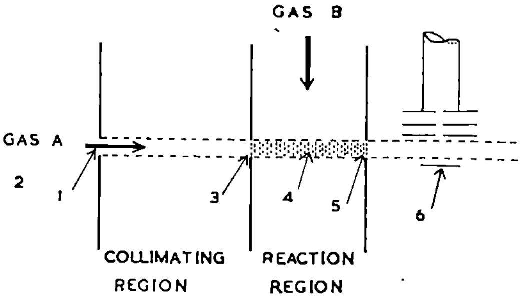

Fig. 1

This technique has been used for the study of the reaction of excited oxygen atoms with nitrogen dioxide:

$$O^* + NO_2 \rightarrow O_2 + NO \qquad (1)$$

The atomic oxygen was produced by an electrodeless radio-frequency discharge (10 Mc./sec.) through oxygen gas at 0·1 mm. mercury pressure in a tubular, hard-glass discharge tube. A round hole, 2·46 mm. diameter in the end of the tube, served as the first aperture, 1, of the molecular beam system. The molecular beam collimating system and the mass-spectrometer have been described elsewhere[1]. Mass-spectrometric study of the molecular beam showed that about 15 per cent of the oxygen molecules were dissociated into atoms, which were almost entirely in a metastable, electronically excited state with 2-eV. excitation energy. Nitrogen dioxide was introduced at a pressure about 10^{-4} mm. mercury into the reaction compartment (compartment C_2 of Fig. 3, ref. 1). Without the discharge operating, and using 70-eV. electrons for ionization in the mass-spectrometer, the ratio of the height of the $m/e = 46$ peak to that of the $m/e = 30$ peak from the nitrogen dioxide was 0·52. When the discharge was switched on, the ratio was reduced to 0·42, indicating formation of nitrous oxide by collisions of the atomic oxygen beam with nitrogen dioxide in the reaction zone. Exact quantitative assessment of the reaction efficiency of the collision process must await more precise measurements, but the preliminary figures suggest that the efficiency is considerably greater than the minimum limit of 1 reactive collision in 100 collisions proposed by Kistiakowsky and Kydd[2] for ground-state oxygen atoms.

While these preliminary results have served to demonstrate the potentialities of the technique, application is, at present, limited to collision processes having high reaction efficiencies. This restriction arises from the relatively small mass-spectrum peaks of reactant *B*, obtained with the technique described above. Preliminary experiments have shown that some improvement may be achieved by introducing reactant *B* also as a molecular beam aligned to intersect the beam of *A* in the reaction zone. Application of the technique to reactions with large activation energies may be possible by simulation of high-temperature conditions by the use of fast molecular beams of reactant *A*.

We record our appreciation of the helpful discussions and continued interest of Dr. W. J. Dunning and Prof. F. H. Garner during the development of the technique. One of us (A. J. B.) is indebted to the Department of Scientific and Industrial Research for a research scholarship.

Average Extinction Coefficient for Re-absorption of Fluorescence Radiation through Uranin Solution

The absorption and the fluorescence spectra of fluorescein in alkali solution overlap considerably. This overlap introduces a certain amount of error in the measurement of intensity of fluorescence in so far as it is not directly proportional to the incident radiation absorbed by the solution. If a fluorescent quantum is emitted somewhere deep in the solution, then during its passage from its point of emission to a measuring device like a photocell, there is a chance that it will be repeatedly re-absorbed and re-emitted by the solution. The consequence of this process is that the average life-time of the excited molecule is increased[1], as each absorption gives a fresh lease of life of about 10^{-8} sec. The effect will be greater, the higher the concentration of the fluorescing solution. Since intensity of fluorescence is directly proportional to the life-time, τ, of the fluorescent molecule under a given set of conditions $\tau_1/\tau_2 = F_1/F_2$, the intensity as measured by the photocell will not be the true intensity. The effect has been explained in different ways[1-3].

To assess the effect of the absorption–re-emission process, it is desirable to know ε_2, the extinction coefficient for the re-absorption of secondary radiation by the experimental solution. The usual method for the determination of the extinction coefficient cannot be applied in the determination of ε_2 because of the polychromatic nature of the fluorescence radiation, the band-spread of which is nearly 1μ in the green region. A plot of $\log I_0/I$ versus C for a constant solution thickness, l, does not give a straight line as obtained for a solution obeying Lambert–Beer's law using monochromatic radiation. Besides this, the secondary re-emission process may also have some effect. That the latter effect is not so important can be shown by comparing measurements for a quenched and an unquenched solution under identical experimental conditions.

The Phoenix light-scattering instrument model 1,000, with single photomultiplier, was adapted for fluorescence measurements by inserting a filter transmitting 3650 Å. in the incident light beam. The photomultiplier was set at 90° to the incident beam. An alkaline fluorescein solution of appropriate strength ($1{\cdot}0 \times 10^{-4}$ *M*) was placed in a cell, 2 cm. wide and 3·7 cm. long. It was placed so that the incident beam fell just near the edge of the shorter side of the cell, exciting fluorescence radiation along the length of the solution. The longer side of the cell, facing the photomultiplier, was covered with black paper except for a small rectangular opening (0·3 mm. wide) to allow the fluorescent radiation to escape. This acted as a source of fluorescence radiation.

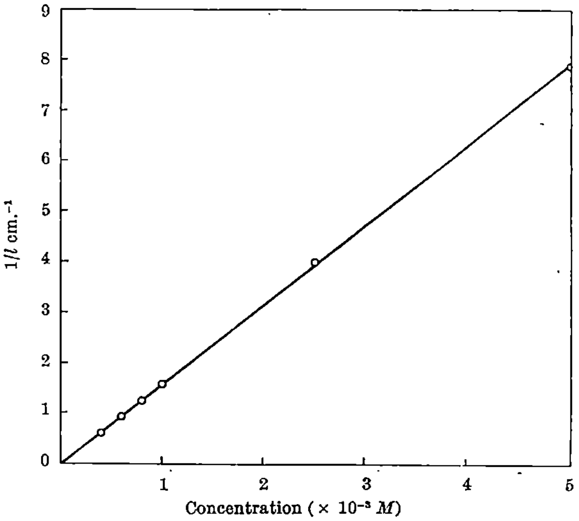

Fig. 1

Another cell of the same dimensions was placed in juxtaposition to the emitting cell, snugly between the latter and the photomultiplier. A yellow gelatine filter was placed in front of the photomultiplier to cut off any scattered primary radiation. The second cell contained alkaline fluorescein solution of various concentrations and the intensity of transmitted light was measured against water as the solvent blank. The plot of $\log I_0/I$ versus C was a curved line. The curvature was still there, when the same amount of potassium iodide solution was added to all the solutions to quench the fluorescence.

Now Lambert's law is known to have no exception. But for a diffuse, polychromatic and faint source like the fluorescence radiation, the use of cells of different dimensions to change the depth of the solution will mean introduction of an air gap between the source and the solution or between the solution and the photomultiplier. This will mean a loss of fluorescence radiation due to change in refractive index at the cell-air interface. To avoid this, the light-path was varied by inserting microscope glass-slides of known thicknesses into the 2-cm. cell placed next to the emitting cell. For each variation of light-path, l, readings were taken with the solvent blank (water) giving 100 per cent deflexion in the galvanometer. It was then replaced by the solution of known concentration, C, and the transmission of fluorescent light was measured in terms of galvanometer deflexion. For a given thickness, transmission was measured for different concentrations of the solutions ranging from 5×10^{-5} *M* to 1×10^{-2} *M*. By this technique, the thickness of the solution could be varied from 2 cm. to 0·05 cm.

For each concentration, the percentage transmission was plotted against the solution thickness. Curved lines were obtained, the curvature increasing with the concentration. The plot of $\log I_0/I$ against l was also curved because of the polychromatic nature of the radiation.

From a re-arrangement of Lambert–Beer's law we have :

$$\frac{1}{l} = \frac{\varepsilon_2 C}{\log I_0/I}$$

For a fixed percentage transmission, say 50 per cent:

$$\frac{1}{l} = \frac{\varepsilon_2 C}{\log 2} = \frac{\varepsilon_2}{0{\cdot}3010} C$$

Therefore, a plot of $1/l$ versus C should be a straight line passing through the origin. The slope of this line will be equal to $\varepsilon_2/0{\cdot}3010$ from which ε_2 can be calculated. The value so obtained will be the average value of the molar extinction coefficient over the whole wave-length range of fluorescence radiation.

The experimental data are plotted in Fig. 1. From the graph the slope of the straight line, $\varepsilon_2/0{\cdot}3010 = 1{,}600$ l.mole^{-1} cm.$^{-1}$ Therefore, $\varepsilon_2 = 481{\cdot}6$ l.mole^{-1} cm.$^{-1}$.

This method takes advantage of the fact that the total number of absorbing centres throughout the experiment remains constant, so that all the interfering effects cancel out. Virtually, the experiment is carried out at a constant value of Cl in accord with the general principle of visual colorimeters. Further calculations show that the value of ε_2 so obtained is a function of the optical density of the measured solution.

Polarization of Triplet→Singlet Emission Spectra

PHOSPHORESCENCE in homogeneous rigid media was identified by Lewis, Kasha and Calvin[1] during 1941–45 as triplet→singlet emission spectra. Simultaneously Weisman and Lipkin[2] were able to show by a wide-angle interference technique that these emissions are electric dipole transitions. Following these investigations, selection rules for triplet–singlet transitions, based on the triplet states undergoing spin-orbit coupling due to the spin magnetic moment of the electrons interacting with the molecular field, were given by McClure[3] and placed on a rigorous basis by Weisman[4]. Recently, Hutchison and Mangum[5], by observing paramagnetic resonance absorption in the phosphorescent state of naphthalene, have confirmed the triplet assignment.

The triplet–singlet transitions, forbidden by multiplicity selection rules, can be made allowed by the spin-orbit perturbations, which mixes states of different multiplicity. Thus the emitting triplet state, T, can be perturbed by one or more of the singlet states, S_k, through spin-orbit coupling and acquire a singlet character, the transition to the ground-state, S_0, being allowed by this singlet character. Since the components of the spin-orbit coupling operator, $(\text{grad } \mathbf{V} \times \mathbf{P}) \cdot \mathbf{S}$, transform like the components of the rotation operator, S_k should have the same symmetry as the product of symmetries of T and the rotation operator. According to this scheme the $T \rightarrow S_0$ spectrum should be polarized parallel to the $S_0 \rightarrow S_k$ absorption. Further, it should be parallel or perpendicular to other singlet–singlet transitions in the molecule depending on whether they are parallel or perpendicular to $S_0 \rightarrow S_k$. This can be confirmed directly, in favourable cases, by measuring the relative polarization of triplet→singlet bands with respect to any two mutually perpendicularly polarized singlet–singlet absorption bands in the molecule. While there is strong indirect evidence[1] from life-time measurements and heavy-atom effects for spin-orbit coupling perturbations in molecules, there is no direct confirmation of the mixing of the triplet with the singlet states, since polarization work up to now[6,11] has involved molecules where unambiguous theoretical prediction and experiment have not been possible.

Pyrazine, , is well suited for such an experiment for the following reasons. (1) the triplet→singlet emission has been assigned beyond doubt[7] as ${}^3B_{2u}(n,\pi^*)\rightarrow{}^1A_g$. (2) The two singlet–singlet transitions at 3300 Å. and 2600 Å. corresponding to ${}^1B_{2u}(n,\pi^*)\leftarrow{}^1A_g$ and ${}^1B_{3u}(\pi,\pi^*)\leftarrow{}^1A_g$ are well separated and their polarizations are known to be respectively along the axis perpendicular to the plane of the ring[8]; and perpendicular to the N—N axis but in the plane of molecule[9]. (3) It is predicted[10] unambiguously from the rotational nature of the spin-orbit coupling operator that all planar azine $\pi^*\rightarrow n$ triplet→singlet emissions should be polarized in the plane of the molecule, and in the case of pyrazine the nodal properties of the π^* and n orbitals lead to the prediction that the triplet→singlet emission should be polarized along the N—N axis[10], that is, perpendicular to both the singlet–singlet transitions at 3300 Å. and 2600 Å.

We have determined the polarization of the triplet→singlet emission spectrum throughout the band system relative to the ${}^1B_{2u}(n,\pi^*)\leftarrow{}^1A_g$ and to the ${}^1B_{3u}(\pi,\pi^*)\leftarrow{}^1A_g$ absorptions. The method consists in exciting into each of the absorption band systems using narrow band monochromatic polarized light at 77° K. in thin (1–3 mm. thick) rigid media and measuring the polarization of the resulting phosphorescence. Great care has been taken to reduce rotational depolarization, and under the experimental conditions this is small in spite of the long life-time of the phosphorescence. The degree of polarization, defined as $P = \dfrac{I_{\parallel} - I_{\perp}}{I_{\parallel} + I_{\perp}}$, where $I_{\parallel}$ and $I_{\perp}$ are intensities of the emitted radiation parallel and perpendicular to the electric vector of the polarized exciting light, theoretically is $0{\cdot}50$ if the emission is polarized parallel to, and $-0{\cdot}33$ if it is polarized perpendicular to, the polarization of the exciting radiation[11]. In pyrazine for ${}^1B_{2u}(n,\pi^*)\leftarrow{}^1A_g$ and ${}^1B_{3u}(\pi,\pi^*)\leftarrow{}^1A_g$ excitations, P for the ${}^3B_{2u}(n,\pi^*)\rightarrow{}^1A_g$ phosphorescence emission is found to be $-0{\cdot}26$. The deviation from the ideal value of $-0{\cdot}33$ is probably due to depolarization factors in the optical system and in the rigid media and not due to the inherent nature of the emission. The above results leave only one possibility for the polarization of the triplet→singlet emission of pyrazine: along the N—N axis of the molecule, confirming the predicted spin-orbit coupling scheme in this molecule.

Further, experiments on the pyrimidine  $\pi^* \rightarrow n$ phosphorescence emission also conclusively yield in plane polarization, conforming to the spin-orbit coupling prediction. A detailed account of this work will be published in the *Journal of Chemical Physics*.

Deterioration of Solid-coated Capillary Columns on Standing

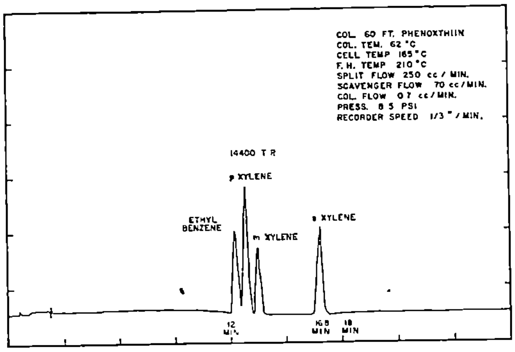
The recent introduction of capillary columns, which are able to give efficiencies of up to 1,000,000 theoretical plates[1], has given a great stimulus to the technique of gas chromatography. Many separations, heretofore impossible with packed columns, are extremely simple when capillary columns are used.

Although we have generally been successful with capillaries, we have recently noted a disturbing phenomenon when using them. The phenomenon referred to is the fact that at least some solid-capillaries will undergo a severe diminution of column efficiency on standing.

Fig. 1 shows the performance of a newly prepared 60 phenoxythiin capillary column. The column was prepared by coating a 0·010 in. internal diameter stainless steel capillary with 10–12 mgm. of phenoxythiin. 10 ml. of a 10 weight per cent solution of phenoxythiin in ethylene chloride were passed slowly through the column under a pressure of 10 p.s.i.g. of nitrogen. After the excess solution had all passed through the capillary, the flow of nitrogen was maintained overnight, at room temperature. The column was then conditioned for 4 hr. at 60° C. and then put into service, with the result shown in Fig. 1. The column continued to give equivalent performance for four weeks, during which time at least fifty samples were analysed on it.

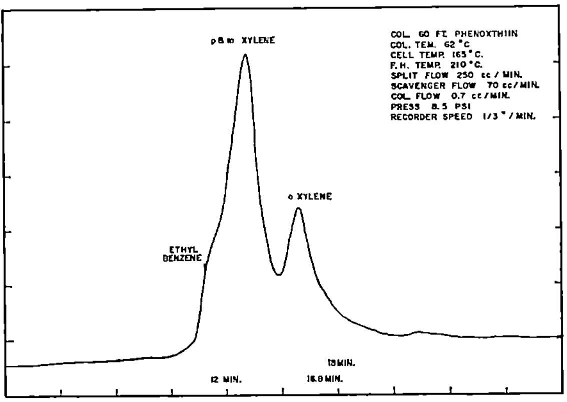
The column was then taken from the chromatograph and stored (at room temperature) for six months. Both ends of the column were opened to the atmosphere during storage.

On attempting to re-use this column, we noted the extreme deterioration of efficiency shown in Fig. 2, which is a run made under identical conditions, with the same column and the sample as the run shown in Fig. 1. While the lack of resolution in Fig. 2 makes it difficult to calculate column efficiency exactly, a rough calculation indicates that the efficiency has dropped from 14,400 theoretical plates in Fig. 1 to not more than 200 theoretical in Fig. 2.



Time

Fig. 1



Time

Fig. 2

A similar behaviour has been observed with columns coated with 7,8-benzoquinoline, another solid material. The deterioration of column efficiency was as extreme with this material as with the phenoxythiin.

We are at a loss to give a full explanation for this phenomenon. Two possibilities present themselves: (*a*) both the phenoxythiin and the 7,8-benzoquinoline were exposed to atmospheric oxygen during the standing period for at least six months and were hence subject to oxidation or other processes of decomposition; (*b*) on removal of the column from the heated chromatographic oven, and subsequent cooling, the substrates may have recrystallized in such a fashion that on re-melting they formed globules instead of a uniform coating. In support of the second possibility, we have noted that the appearance of Fig. 2 is strikingly similar to chromatograms made with glass capillaries, where we could observe the presence of substrate globules.

Fortunately, this behaviour appears to be restricted to solid-coated capillaries. We have not observed it in any of the liquid-coated (squalane, tri-cresyl phosphate, dioctyl sebacate) capillaries we have made. While it would be premature to predict such behaviour for all solid substrates, it does appear that this is a point worth further investigation, since phenoxythiin and 7,8-benzoquinoline are two of the most effective separators yet found for the lower aromatics.

Adducts of Urea and Thiourea obtained by means of a Sublimation Technique

THE classical methods for obtaining adducts of urea and thiourea with some classes of organic substances imply the use of aqueous or alcoholic solutions of 'reagents' (urea or thiourea). Other methods have been described more recently by which adduction is obtained by mixing solid urea directly with the proper 'reactant'[1].

It has been found that the adduction of the urea-hydrocarbon type is actually a two-phase process involving urea in the solid state. The solvents for urea seem to have no function other than that of precipitating the reagent in the finely divided form suitable for interaction with the hydrocarbon[2].

All the adduction processes with solid urea usually require an appreciable induction time, which is necessary for the transition of the reagent from its normal crystalline form to that of the adduct including the reactant molecules. This induction time is usually shortened by reducing the urea in minute particles and adding small quantities of acetone or other simple ketones. The catalytic action of acetone is explained by way of having a part in the formation of an intermediate unstable adduct with urea[3].

In order to perform an adduction process with highly divided solid reagent, avoiding any mechanical stress on the adduct, we directly condense sublimated urea (or thiourea) on the liquid reactant placed on a cooled surface. The sublimated urea and thiourea, when in contact with an adductible material, crystallize around the matrix molecules as adduct, while, if some non-adductible material is placed on the cold surface, recondensation of urea and thiourea takes place in the normal crystalline form (tetragonal and orthorhombic respectively).

The process, which is actually rather fast, may be easily followed and successfully used for analytical purposes making use of the differences between the infra-red spectra of urea (and thiourea) in the normal crystalline form and in the adduct form[4–7]. The infra-red spectrum of the suspension obtained through adduction (in excess of reactant) clearly reveals whether an adduction has taken place. The spectrum may show also an excess of reactant, which in general does not disturb the detection of the main bands of the adduct. The excess reactant, anyway, can be washed away with pentane. In most cases the potassium bromide (sodium chloride for thiourea) pressed disks technique can be used without decomposition of the adducts.

The present technique of adduction 'via sublimation' may be performed with high-boiling adductible liquid molecules in a conventional laboratory sublimator using the vacuum supplied by a rotary oil pump. At a pressure of 0·1 mm. mercury, the experimental temperature is about 120° C. for urea and 140° C. for thiourea.

I have used this technique with a number of compounds. With urea I have adducted straight-chain paraffins, saturated and unsaturated fatty acids and esters as well as some alcohols and ketones. With thiourea I adducted several branched paraffins and naphthenic hydrocarbons.

The method is useful for the investigation of the adductibility of pure substances, thus providing information about their molecular shapes. The quantity of the product required is about 1 mgm. or less.

Furthermore, it is possible to detect small quantities of adductible materials in complex mixtures. For example, in a 1 per cent mixture of cetane in decaline the sublimated urea condensates in the hexagonal form (adduct), apparently until molecules of cetane are available. Then the condensation of urea takes place in the normal tetragonal form. This fact allows us to extend the investigation to solid materials (for example, higher hydrocarbons and their hydroxylated or carboxylated derivatives), when dissolved in a non-adductible high-boiling liquid.

Care must be taken to avoid in this case the deposition of a too thick layer of sublimated urea (or thiourea) on the liquid surface. As non-adductible solvents I used a high-boiling naphthenic oil for urea and an aromatic oil for thiourea. Although in this case we can find, besides urea or thiourea as adducts, even some reagent in the normal crystalline form, the complexing of the adductible fraction dissolved in the oil may be detected from the inspection of the shape of some characteristic band in the infra-red spectrum of the resulting suspension.

The regions which appear more characteristic for this inspection are near 3,400 cm.$^{-1}$ (ν(N—H) vibrations), near 1,650 cm.$^{-1}$ ($\delta(NH_2) - \nu(C=O)$ vibrations for urea and $\delta(NH_2)$ vibration for thiourea) and in the 700–800 cm.$^{-1}$ range (ν(C—C—N) for urea and $\nu(C=S) - \nu$(N—C—N) for thiourea), as can be seen

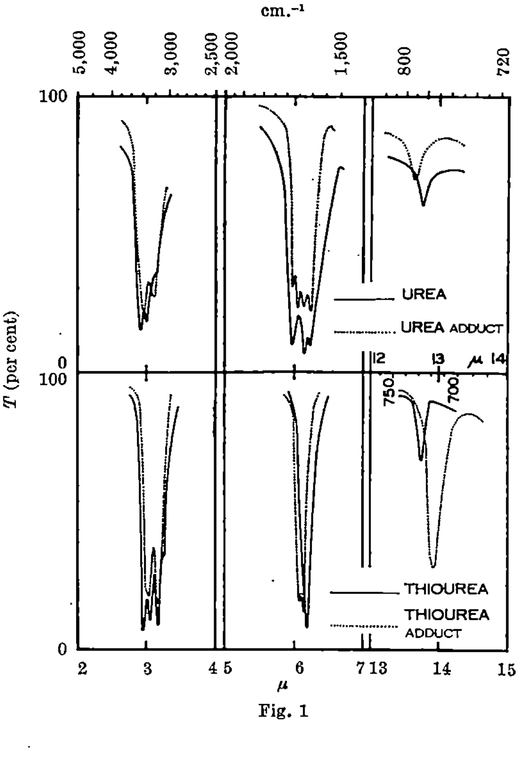

Fig. 1

from Fig. 1. The 3,400 cm.$^{-1}$ region is particularly suitable when hydrocarbons or any of their derivatives not containing —OH or —NH— groups are investigated about adductibility versus urea or thiourea or are employed as solvents for solid materials.

BIOCHEMISTRY

Chromatographic Separation of Biologically Active Components from Commercial Trypan Blue

Trypan blue has been shown to produce reticulosis and reticulo-sarcoma as well as congenital malformations when injected subcutaneously into rats[1,2]. Considerable differences in the biological activity of various commercial preparations of trypan blue have been found, and it has been suggested that these are due to variations in the amount and kind of impurities present[3,4]. Commercial trypan blue is known to contain a red impurity which is more diffusible than trypan blue itself and which is excreted rapidly in the urine[5-7]. This material has been separated from trypan blue by extraction with ethyl alcohol[8] or with acetone[7] or by passing through a cellulose column[7,9]. Although this red fraction causes some resorptions, when injected into pregnant rats, it does not appear to produce congenital malformations[4,9]. This suggests the possible presence of other active impurities in trypan blue.

We have fractionated commercial trypan blue (Merck) on alumina and have separated a purple impurity in addition to the red fraction. The former was highly active in inducing reticulosis in rats, whereas the latter was inactive. Purified trypan blue itself showed only slight activity. The crude dye (6 mgm. in 6 ml. methylethylketone/water/ethanol 75:25:10) was placed on a column (12 × 2·2 cm.) of alumina (B.D.H. or Merck, 50 gm.) and eluted successively with methylethylketone/water/ethanol (75:25:10), water and 0·01 *N* sodium hydroxide. The methylethylketone/water/ethanol eluted first a reddish fraction ($\lambda_{max.}$ 560mμ), followed by the main blue fraction ($\lambda_{max.}$ 600 mμ). Water eluted a single purple fraction ($\lambda_{max.}$ 570 mμ) as did 0·01 *N* sodium hydroxide. The contribution of the various fractions to the absorption of the crude dye at 580 mμ is shown in Table 1.

The red and blue fractions each gave a single band when rechromatographed on alumina. The former could, however, be resolved into two components, a faster moving red-violet dye and a slower blue-violet dye, by paper chromatography with 80 per cent aqueous ethanol as solvent. In this system the blue fraction moved very slowly and the purple fraction not at all. On rechromatographing the purple fraction on alumina, approximately half the material could be eluted with water; the remainder only came off with 0·01 *N* sodium hydroxide. It thus appears as if the sodium hydroxide fraction were derived from the water fraction as a result of irreversible adsorption of the dye on alumina.

Table 1. Relative Contribution of Various Fractions to the Optical Absorption of Crude Trypan Blue at 580 mμ

	Per cent
Red (violet)	12
Blue	76
Purple (water fraction)	5
Purple (sodium hydroxide fraction)	7

In order to prepare sufficient of the various fractions for biological testing 10 gm. of Merck's trypan blue was applied as a 0·5 per cent solution in methylethylketone/water/ethanol (75:25:10) to an alumina column (12 × 4·5 cm.) Under these conditions the violet components (red fraction) passed through the column without hold-up, while the blue fraction was retained until the column was saturated with blue dye. It was then eluted with methylethylketone/water/ethanol solvent. The purple fraction was finally eluted with water, and the material which remained on the column was discarded.

After removal of the solvent, each of these fractions was tested for its power to induce proliferation of the reticulo-endothelial system of rat liver, in a group of five female rats of the same age. The red fraction was used as a 0·5 per cent solution, and the blue and purple fractions as 1 per cent solutions in distilled water. Each rat received two subcutaneous injections of 1 ml. at an interval of a fortnight, and all rats were killed seven days after the last injection, that is 21 days after the beginning of the experiment. A further group of five rats served as controls and was treated with crude trypan blue (1 per cent) in the same manner.

No observable reticulosis developed in any of the five rats treated with the red fraction. The blue fraction caused a mild portal reticulosis which was very much less marked than that observed in rats treated with crude trypan blue. In each of the five rats the purple fraction produced an intense portal as well as an intralobular reticulosis associated with the formation of numerous small cysts in the portal tract. In some regions, there was increased vascularity between the small cysts, leading to collapse of the cysts and accentuation of the portal reticulosis. The reticulosis produced by the purple fraction was of far greater intensity than that observed in the animals treated with the unfractionated trypan blue.

From these results it appears that the activity, so far as proliferation of the reticulo-endothelial cells of rat liver is concerned, is associated with the purple fraction. The chromatographic behaviour of this active fraction differs considerably from that of the well-known red fraction, which was separated by 80 per cent ethanol into two components and which appears to be inactive with respect to induction of reticulosis as well as to production of congenital malformations. Trypan blue itself has only slight activity ; but the possibility that its activity is due to contamination with purple dye cannot be excluded.

Elucidation of the structures of the various components of trypan blue is in progress.

Our thanks are due to Dr. Christine Gilbert, who was responsible for the animal experimental aspects of the project, and to Dr. H. M. Schwartz and Dr.

Stimulation of Lipogenesis in Thyroid Tissue *in vitro* by Free Fatty Acids

Recently, it has been demonstrated that some of the *in vitro* actions of certain pituitary hormones on adipose tissue can be reproduced by simple supplementation of the suspending medium with albumin-complexed free fatty acids[1]. This has prompted a more generalized analysis of the effects of free fatty acids on the metabolism of surviving preparations of target endocrine glands. We have incubated slices of sheep and human thyroid tissue at 38° C. and *p*H 7·4 in modified Krebs–Ringer *tris*-phosphate or Krebs–Ringer bicarbonate[2] containing 2 mgm./ml. of uniformly labelled glucose (glucose-U-^{14}C), 10 mgm./ml. of fat-free bovine albumin[3], and varying quantities of sodium oleate. Direct chemical analysis[4] disclosed that such exogenous supplementation with oleate augmented the thyroidal pool of free fatty acids. The associated striking increases in lipogenesis from glucose-U-^{14}C form the basis of the present report.

Following 3 hr. incubation, thyroid slices were frozen with liquid nitrogen and extracted for total lipids as described previously[3]. Washed extracts were partitioned into neutral lipids and phospholipids with silicic acid columns[5] and aliquots of the fractions were assayed for radioactivity with an automatic Packard 'Tri-Carb' liquid scintillation counter (Packard Instrument Co., Inc., La Grange, Ill.). The remaining portions were hydrolysed for 6 hr. at 100° C. with 6 *N* hydrochloric acid–50 per cent ethyl alcohol. Fatty acids and non-saponifiable lipids were removed by three extractions with petroleum ether and pooled ether extracts were washed, evaporated to dryness and re-suspended for radioactive assay. The aqueous residues of the hydrolysates were evaporated *in vacuo* and re-suspended in water for resolution on paper by ionophoresis (*p*H 3·6; pyridine–acetic acid–water 1 : 10 : 89 v/v) and by chromatography (ethanol–water 8 : 1 v/v). Radioactive moieties on ionophoretograms and chromatograms were localized by radioautography and appropriate segments of paper were cut out for direct counting in the liquid scintillation counter. Recovery standards of glycerol-1-^{14}C were processed with each experiment to correct for losses of glycerol through volatilization and degradation[7] during preparative manipulations.

In Krebs–Ringer bicarbonate as well as Krebs–Ringer *tris*-phosphate, total lipogenesis from glucose-U-^{14}C by surviving thyroid slices was augmented two- to three-fold in the presence of 1 μM/ml. of albumin-complexed oleate. The stimulation was largely effected by a four- to five-fold increase in the radioactivity of the neutral lipid fraction (Table 1). Conjoint analyses to be presented elsewhere indicated that the enhanced lipogenesis was accompanied by a small rise in oxygen consumption, an inconstant alteration in glucose-assimilation, a reduction in the oxidative decarboxylation of glucose-U-^{14}C, and an increased formation of lactic acid-^{14}C from the labelled glucose. Less-prominent, albeit still significant, increases in the incorporation of glucose into thyroid lipids were obtained with higher concentrations of oleate (4–6 μM/ml.) which depressed Q_{O_2}. Analysis of aqueous residues following acid hydrolysis disclosed that glycerol-^{14}C (as glycerol or glycerophosphate) accounted for more than half the lipid radioactivity. Formation of glycerol from glucose-U-^{14}C was enhanced by 1 μM/ml. oleate; the increase was chiefly channelled into the neutral lipid fraction (Table 2). Oleate also stimulated the incorporation of radioactivity into neutral lipid components which retained solubility in petroleum ether following acid hydrolysis (Table 2). Alkaline hydrolysis disclosed that this increase consisted principally in fatty acids rather than non-saponifiable lipids.

From all the foregoing, it is apparent that exogenous supplementation of intra-thyroidal fatty acids results in striking changes in lipogenesis. The

Table 1. Effects of Albumin-complexed Oleate on the Incorporation of Glucose-U-^{14}C into the Lipid Fractions of Thyroid Slices

Exp. No.	Species	Medium †	μgm. glucose-U-^{14}C/gm. initial weight to:*			
			Phospholipid		Neutral lipid	
			A	*B*	*A*	*B*

6	2·1	1·0	—	—	6·8	19·5	9·5	26·2

* Experiments are the same as in Table 1. Phospholipid and neutral lipid fractions were hydrolysed with 6 *N* hydrochloric acid–50 per cent ethyl alcohol. Acid hydrolysates were resolved into radioactive components which retained solubility in petroleum ether or which exhibited the chromatographic and ionophoretic properties of glycerol or glycerophosphate (glycerol). The (*B*) or (*A*) denotes the respective presence or absence of sodium oleate in suspending media during incubation.

phenomenon is somewhat similar to the "experimental aberrant lipogenesis" which has been described by Cogan and Kuwabara following 24–48 hr. of incubation of tissue 'buttons' with serum and sodium oleate[7]. However, in their system, increased sudanophilic material was not observed with thyroid preparations.

For the moment, the biochemical basis for the effects of albumin-complexed oleate must remain conjectural. The existence of intra-thyroidal mechanisms for the activation of fatty acids may be inferred from the finding in this Laboratory that surviving sheep thyroid slices can esterify and oxidize albumin-complexed palmitate-^{14}C (ref. 2). Unless such activation were rate-limiting, it is conceivable that an increased availability of free fatty acids could abet lipogenesis in several ways. First, it could provide long-chain coenzyme A derivatives for esterification of glycerophosphate[8]. Indeed, the plethora of acylated fatty acids might also compete successfully with cytidine derivatives for the unesterified carbon of the α,β-diglycerides[8] and thus account for the predominant impact on the neutral lipid fraction. Since phospholipid components were not fractionated in the present work, one cannot assess whether the occasional modest stimulation of phospholipid radioactivity proceeded beyond phosphatidic acid. Secondly, oxidation of an increased quantity of activated fatty acids could indirectly promote the synthesis of fatty acids as well as glycerophosphate from glycolysis. The generation of reduced diphosphopyridine nucleotide during catabolism of fatty acids by β-hydroxyacyl dehydrogenase[9] would provide co-factors for the former[10], and would enhance the formation of the latter from dihydroxy acetone phosphate since the equilibrium constant of soluble glycerophosphate dehydrogenase already favours this direction[11]. Differentiation between the above speculative possibilities (that is, metabolic changes secondary to the disposition of free fatty acids) and other potential actions of fatty acids[12] (that is, surface-active effects which may not entail prior activation) must await further investigation.

Biosynthesis of Polyenoic Fatty Acids in Human Whole Blood

IT has been known for some time now that human blood cells are able to incorporate acetate-1-^{14}C into blood lipids[1,2]. James *et al.*[2,3] found the incorporation of radioactive acetate into the saturated as well as into the unsaturated fatty acids of blood lipids, including the 'essential fatty acids'. Based on these experiments, the authors concluded that a total synthesis of essential fatty acids in human blood would be possible. Klenk[4] and Mead *et al.*[5] showed that the C_{20}- and C_{22}-polyenoic fatty acids in rat liver originate from exogenous linoleic and linolenic acids by extension of the carbon chain by acetate units starting at the carboxylic group. In addition, new double bonds are introduced in the divinylmethane-rhythm in direction towards the acid group. This mechanism is valid for polyenoic acid synthesis in the human liver[6] as well as in the descending classes of vertebrates[7].

In order to find out if polyenoic acids can be synthesized by blood cells in the same way we have incubated human whole blood with acetate-1-^{14}C. The fatty acids were isolated and the unsaturated fraction degraded by oxidative ozonolysis. The resulting dicarboxylic acids were separated by column chromatography and the activity measured in a windowless flow-counter. Results are shown in Table 1 (for methods see refs. 4, 6, 7).

Radioactivity was found almost exclusively in glutaric acid (predominantly from Δ5,8,11,14-eicosatetraenoic acid = arachidonic acid), succinic acid (predominantly from Δ4,7,10,13,16,19-docosahexaenoic acid) and in the higher dicarboxylic acids, mainly azelaic acid (from oleic, linoleic and linolenic acids). On the contrary, malonic acid originating from the central parts of the polyunsaturated carbon chains showed only minute activity. This low activity seems to exclude the total synthesis of linoleic and linolenic acids which might be concluded from the activity of azelaic acid. Although degradation and re-extension reactions at the carboxylic end of linoleic and linolenic acids could contribute to the incorporation of this activity, it will originate mainly from oleic acid.

The results strongly support the mode of formation of polyenoic fatty acids outlined here, which seems also to be valid for their biosynthesis in human blood. We hope to obtain further support of these results by reductive ozonolysis of the unsaturated fatty acids

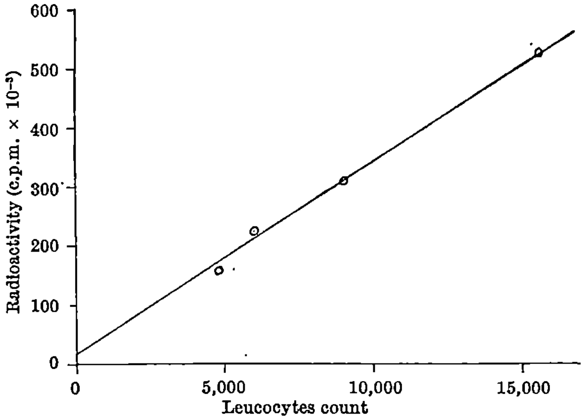

Fig. 1. Relation between total activity of fatty acids from human whole blood after incubation with acetate-1-^{14}C and leucocyte count

Table 1. SPECIFIC ACTIVITY OF DICARBOXYLIC ACIDS FROM OXIDATIVE OZONOLYSIS OF UNSATURATED FATTY ACIDS FROM HUMAN WHOLE BLOOD AFTER INCUBATION WITH ACETATE-1-^{14}C

In each case 50 ml. of freshly drawn blood were heparinized and after addition of 15 mgm. glucose and 0·23 mc. = 8·35 mgm. acetate-1-^{14}C incubated for 5 hr. at 37°. Yields in mole per mole polyenoic acid; specific activity in counts/min. and mgm.

Experiment	Higher M.W. dicarboxylic acids (azelaic acid)		Glutaric acid		Succinic acid		Malonic acid	
	Yield	C.p.m./mgm.	Yield	C.p.m./mgm.	Yield	C.p.m./mgm.	Yield	C.p.m./mgm.
1	0·54	1,275	0·12	655	0·07	532	0·15	28
2	0·51	4,230	0·12	1,240	0·08	1,195	0·43	63

4	0·59	3,810	0·10	1,980	0·08	1,620	0·32	68

and subsequent activity measurement of the degradation products derived from the methyl end[7].

It was suggested previously that the fatty acid synthesis in human blood occurs predominantly in erythrocytes. More recently several authors have given evidence for lipid synthesis mainly in leucocytes[8-10]. Besides, these platelets[10] and reticulocytes[9,10] seemed to be involved in fatty acid synthesis too. In the course of our investigations we obtained evidence for synthesis of fatty acids in human blood linked predominantly to leucocytes. Since our experimental conditions for the incubation of blood from subjects with different leucocyte counts were kept constant, we were able to compare leucocyte count and incorporation of radioactivity into the total fatty acids (Fig. 1).

Surprisingly enough we found good linearity between leucocyte count and total incorporated activity.

Oxidation-Reduction Reactions of Plastoquinone in Isolated Chloroplasts

QUINONES have previously been implicated as oxidation-reduction carriers in the photosynthetic electron transport system on the assumption that chloroplasts of higher plants contained vitamin K_1[1-3]. It has now been shown that chloroplasts contain little or no vitamin K_1 but that another quinone, 2,3-dimethyl-5-solanesyl-benzoquinone, is present in relatively large amounts[4-6]. This quinone is known as plastoquinone, Q_{255} and Kofler's quinone.

Evidence that plastoquinone functions in the electron transport system associated with photosynthesis has been presented by Bishop[6], who has shown that it will restore photolytic activity when added to spinach chloroplasts which have been extracted with organic solvents. Recently, Crane *et al.*[7] have claimed that exposure of spinach chloroplasts to light resulted in an 80 per cent reduction of the endogenous plastoquinone. In the present communication we provide some further observations on the oxidation-reduction reactions of endogenous plastoquinone in isolated chloroplasts.

Chloroplasts were isolated from sugar-beet leaves (var. Sharp's Klein Wanzleben *E*) by the method of Mayer and Friend[8], except that the isolation medium was buffered to *p*H 7·8 with 0·05 *M* sodium/potassium phosphate instead of *tris*-hydrogen chloride. The chloroplasts (0·4–0·8 mgm. chlorophyll/ml.) were suspended in a medium containing 0·4 *M* sucrose, 0·01 *M* potassium chloride and 0·05 *M* sodium/potassium phosphate, *p*H 7·0.

Plastoquinone was extracted by a modification of the method[9] used for the extraction of ubiquinone from mitochondrial preparations, and the oxidation-reduction state of the quinone measured by the change in extinction at 255 mμ after the addition of sodium borohydride.

The concentration of plastoquinone in the chloroplasts was 9 μmoles/gm. protein or 0·1 mole per mole chlorophyll. This concentration agrees with that determined in spinach chloroplasts by Crane *et al.*[7]. There was no evidence for the presence of vitamin K_1. It is interesting to compare this concentration with that of another electron carrier in the chloroplast, cytochrome *f*. It has been shown[10,11] that the molar ratio of chlorophyll to cytochrome *f* in a number of chloroplast preparations is about 200–400. Thus the molar concentration of plastoquinone exceeds that of cytochrome *f* by a factor of 20–40. In this connexion, it is interesting to note that a related quinone, ubiquinone (coenzyme Q), in mitochondria is also present in a considerable molar excess over the individual cytochromes in mitochondria.

The oxidation-level of plastoquinone (that is, percentage of total in oxidized form) in freshly isolated chloroplasts varied between 45 and 90 per cent; the oxidation-level appeared to increase as the chloroplasts aged. Illumination (5 min. at 3,200 ft.-candles) resulted in a fall of the level to 35–65 per cent. Thus there had been approximately only 15 per cent reduction of the quinone. Crane *et al.*[7], on the other hand, have reported an 80 per cent reduction in a spinach chloroplast preparation incubated under similar conditions. The reason for this discrepancy is not apparent at the moment.

In order to obtain further information on the oxidation-reduction reactions of plastoquinone and its site of action in the electron transport system, the effect of certain natural and artificial electron carriers was studied.

Addition of 2,6-dichlorophenolindophenol (final concentration 0·5 m*M*) to the chloroplasts in the dark converted all the plastoquinone into the oxidized form. When this mixture was illuminated there was

Table 1. REDUCTION OF ENDOGENOUS PLASTOQUINONE IN CHLOROPLASTS BY TPNH

Addition	Incubation		Plastoquinone (per cent in oxidized form)
	Time	Light or dark	
Experiment 1			
None	0	dark	45·8
TPNH	5 min.	dark	26·0
TPNH	5 min.	light	34·3
Experiment 2			
None	0	dark	87·5
None	5 min.	light	73·5
TPN + chloroplast extract	15 min.	dark	80·5
TPN + chloroplast extract	15 min.	light	59·0

The incubation mixture contained 1 ml. chloroplast suspension, 1 ml. chloroplast extract or water, 0·625 mM TPN or TPNH.

5 per cent reduction to the quinol. Thus, under conditions where the Hill reaction is operative, the steady-state level of the plastoquinone is 95 per cent oxidized.

It was found that incubation of the chloroplasts with reduced triphosphopyridine nucleotide (TPNH) in the dark resulted in a reduction (20–30 per cent) of the plastoquinone. A similar reduction could also be brought about by TPNH formed photochemically in a reaction mixture consisting of chloroplasts, triphosphopyridine nucleotide (TPN) and a chloroplast extract containing photosynthetic pyridine nucleotide reductase[12] (Table 1).

These results provide further evidence that plastoquinone is a functional member of the photosynthetic electron transport system. The site of action of the quinone is now under investigation.

Metabolites of Vitamin B_{12} in Bile after Parenteral Administration of the Vitamin

SEVERAL investigations have shown that, in animals and in man[1], the major proportion of the total radioactivity excreted after an injection of radioactive vitamin B_{12} is excreted in the bile, and that in man at least two-thirds of the biliary radioactivity is re-absorbed from the intestine. This indicates that vitamin B_{12} is subject to an entero-hepatic circulation similar to other substances in bile.

Radioactive bile was collected via a bile duct cannula from rats injected with radioactive vitamin B_{12}. Vitamin B_{12} and radioactive cobalt-containing metabolites of B_{12} were extracted from the bile. The acidified bile (pH 2–3) was denatured with 95 per cent ethanol, and any bound B_{12} or B_{12} analogues freed by boiling in water for 15 min. The supernatant, after evaporation to a small volume, was subjected to repeated extractions with chloroform and then the water-phase (pH 2–3), saturated with ammonium sulphate, was extracted with secondary butanol. The secondary butanol phase, after adding ethyl ether, was extracted with water. Having thereby removed most of the pigment and impurities, compounds containing cobalt were adsorbed on activated charcoal, washed with 5 per cent phenol, and then eluted with hot 65 per cent acetone. The eluate was evaporated to a small volume to which some non-radioactive concentrated vitamin B_{12} solution was added for a control spot on the electrophoretogram and chromatogram. Throughout the extraction, the pH was kept at 2–3 and any cobalamines were maintained in the cyano form by the addition of 0·01 per cent sodium cyanide. Two-dimensional separation of the metabolites was attempted by electrophoresis at a potential of 8 V./cm. for 16 hr. on No. 1 Whatman filter paper in a buffer of 0·5 N acetic acid and 0·01 per cent sodium cyanide; followed by descending paper chromatography at right angles to the direction of electrophoresis in a system of water-saturated secondary butanol with 1 per cent acetic acid (w/v) and 0·01 per cent sodium cyanide. The resulting radioactive spots on the chromatogram were resolved by making autoradiographs using X-ray film. The radioactivity in the chromatogram spots was counted in a scintillation counter after elution with water.

Fig. 1 shows the results obtained from a sample of rat bile. The control spot contained only non-radioactive vitamin B_{12}, detected by its colour on the chromatogram, and is represented diagrammatically. The relative amounts of radioactivity contained in

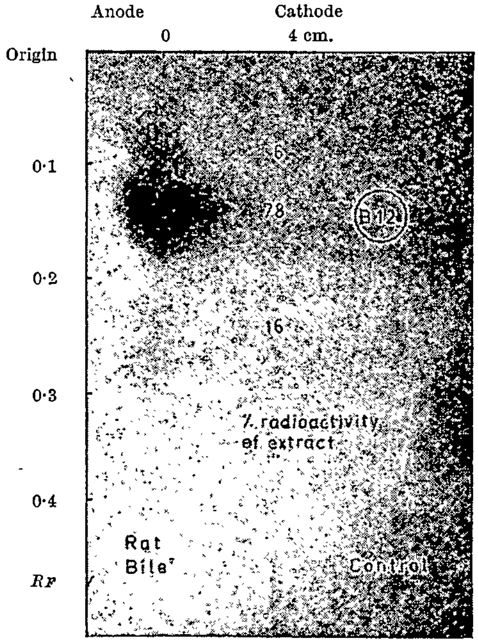

Fig. 1. Autoradiograph of a sample of rat bile following the injection of cobalt-56 vitamin B_{12}

each spot on the chromatogram is shown. A similar result was obtained from a different sample of rat bile.

Comparison with the work of others[2] indicates that the metabolites of vitamin B_{12} here demonstrated in bile are analogues of vitamin B_{12}, and like B_{12} have zero electrophoretic mobility. Free cobalt as cobalt chloride did not migrate in any of the areas shown on the chromatogram. The rat bile contained at least two analogues of vitamin B_{12}. The major portion, approximately three-fourths, of the radioactivity was present as vitamin B_{12}, the remaining fourth being in the B_{12} analogues.

It has been shown by others (see ref. 3) that cyanocobalamine is more readily absorbed in man than the other cobalamines and structural analogues of B_{12}, absorption of the latter being dependent on a strict chemical specificity of the B_{12} benzimidazole group[4]. It seems likely, therefore, that the metabolic products of B_{12} will not be absorbed, or will be poorly re-absorbed once they are excreted in the bile. For this reason, the presence of vitamin B_{12} analogues in bile offers a possible explanation of the appreciable amount of radioactivity sometimes found in the fæces of normal human subjects in the fæcal excretion test of B_{12} absorption[5]. Similarly, it offers an explanation of the finding[1] that re-absorption by the enterohepatic circulation of the radioactivity in human bile after parenteral cobalt-56 vitamin B_{12} was incomplete, being approximately two-thirds of the total radioactivity present.

Non-Enzymic Hydroxylation of Polycyclic Aromatic Hydrocarbons

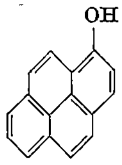
THE hydroxylation of aromatic compounds *in vivo* is well known[1], and polycyclic aromatic hydrocarbons[2] and aromatic amino-acids and related compounds[3] have been found to be hydroxylated by suitably fortified suspensions of rodent liver microsomes. Aromatic amino-acids and related compounds are also hydroxylated non-enzymically in phosphate buffer solutions containing iron and ascorbic acid in the presence of oxygen[4,5], or in hydrogen peroxide solutions containing Fe^{++} (ref. 6). In the case of polycyclic aromatic hydrocarbons slow conversion to quinones, by ascorbic acid[7], and more rapid oxidation by hydrogen peroxide[8], have been reported.

Udenfriend *et al.* claimed[4], and Dalgliesh confirmed[5], that the phenols produced by the non-enzymic hydroxylation of aromatic amino-acids, and related compounds, with a system involving iron, ascorbic acid and oxygen, were identical with the phenols produced during animal metabolism. In view of this and the possible connexion between *in vivo* metabolism of polycyclic aromatic hydrocarbons and carcinogenesis[9] the effect of the Udenfriend system on these compounds was examined. It was found (see Table 1) that a system involving Fe^{++}, a suitable complexing agent and oxygen, in a buffer solution, would readily convert pyrene to 3-hydroxypyrene (3 on Richter's system of nomenclature, but 1-hydroxy on Patterson's system), as follows:

Table 1. CONDITIONS FOR THE HYDROXYLATION OF PYRENE

Reaction system	Yield of phenol (mean of five experiments)
Complete system*	38γ
,, minus Fe^{++}	0
,, ,, EDTA	Trace (< 3γ)
,, ,, Ascorbic acid	28γ
,, ,, Fe^{++} and ascorbic acid	0
,, ,, EDTA and ascorbic acid	Trace (< 3γ)
,, ,, Fe^{++} and EDTA	0
,, but with nitrogen instead of oxygen	0
,, but with acetate buffer instead of phosphate	125γ
,, but with Fe^{+++} instead of Fe^{++}	Trace (< 3γ)

* A solution of 500 mgm. L-ascorbic acid, 250 mgm. ferrous sulphate and 500 mgm. of the disodium salt of ethylenediaminetetraacetic acid (EDTA) in 50 ml. of 0·1 *M* phosphate buffer *p*H 5·8 (or 0·1 *M* acetate buffer *p*H 5·8). Pyrene (2 mgm. in 0·4 ml. of ethanol) was added and oxygen gas bubbled through. The reaction was carried out at a temperature of 95° C. for 1 hr.



3-Hydroxypyrene

Ascorbic acid stimulated the reaction, but Fe^{+++} would not replace Fe^{++} even in the presence of ascorbic acid. This is in contrast to the Udenfriend system and with Mazelis's non-enzymic decarboxylation reaction[10]. Replacement of the phosphate buffer by an acetate buffer led to a three-fold improvement in yield. In the experiment at a lower temperature (38° C.) with the complete system, 8 μgm. of 3-hydroxypyrene were obtained from a reaction lasting 1 hr. With solutions containing the complete reaction system but with the Fe^{++} replaced by Cu^{+}, Cu^{++}, Co^{++}, Ce^{+++}, Mg^{++}, Mn^{++} Hg_2^{++} and Fe^{+++} (the valence state of the metal on introduction into the system is specified) either no, or only a trace of, 3-hydroxypyrene was formed.

The activity of the system was dependent on the choice of complexing agent, as shown in Table 2. The failure of cyanide to inhibit this system is in contrast with the behaviour of Warburg's model enzymes[11], based on iron-containing charcoals and the heavy-metal catalysed 'autoxidation' of ascorbic acid[12]. The effect of the complexing agent is undoubtedly to modify the oxidation-reduction potential

Table 2. EFFECT OF COMPLEXING AGENTS ON THE HYDROXYLATION OF PYRENE

Reaction system	Yield of phenol
Complete system	
,, plus potassium cyanide*	64γ
,, ,, riboflavin	55γ
,, ,, dipyridyl	Trace (< 3γ)
,, ,, *o*-phenanthroline	0
Complete system minus EDTA	
,, plus sodium citrate	26γ
,, ,, dipyridyl	Trace (?)
,, ,, *o*-phenanthroline	Trace (?)
Fe^{++} and riboflavin only	34γ

* 500 mgm. of each complexing agent was added, but a considerable part of the riboflavin failed to dissolve.

of the iron[13], and it is perhaps not without significance that both αα-dipyridyl and *o*-phenanthroline stabilize strongly the ferrous state[14]. Inhibition of the system by these two agents may, however, be due to hydroxylation of the complexing agent. The hydroxylating power of a combination of Fe^{++} and riboflavin must be of considerable biological interest.

3-hydroxypyrene is the phenol produced by the metabolism of pyrene[15] and the 3 position of pyrene is a site of free-radical attack[16]. It has been found during these experiments that naphthacene, chrysene, 1:2-benzanthracene and 3:4-benzopyrene also react under these conditions and work is now in progress to identify these products.

The 3-hydroxypyrene was identified by extracting the cooled reaction mixture with 3 × 50 ml. of ether, and chromatographing the dried ethereal extracts on alumina. On development with ether, any phenols present passed slowly down the column as bands fluorescing under ultra-violet illumination. Pyrene gave rise to a single bright-blue fluorescent band which after collection was evaporated to dryness under reduced pressure, and redissolved in spectroscopic ethanol. Its absorption spectrum (220–420 mμ) and that of its sodium salt proved identical with those of 3-hydroxypyrene and its sodium salt[17]. The yield was calculated from the absorption at 386 mμ and 366 mμ. Small losses occurred on the chromatography columns, and yields of less than 3γ could not be estimated satisfactorily.

Kinetics of the Enzymic Degradation of Deoxyribonucleic Acid into Sub-units

Recent reports from this laboratory[1,2] described the enzymic degradation of deoxyribonucleic acid (DNA) into rod-like sub-units having a molecular weight of 5–6 × 10^5 and a Watson and Crick[3] double helical structure. No production of dialysable nucleotides and no increase of the ultra-violet absorption coefficient at 260 mμ were detectable during the digestion. It is the purpose of this communication to report further information obtained by using a purified enzyme preparation.

The crude enzymic preparation from chicken erythrocytes already described[1,2] was purified several hundred times according to a procedure which will be reported elsewhere[4], and used at activity concentrations about 100 times higher than those of the crude preparation used before. Degradation of chicken erythrocyte DNA (which was exclusively used in this work) by the more active enzyme was characterized by: (1) a first phase in which the molecular weight of DNA (as determined by light scattering[5]) dropped rapidly from its starting value of about 6×10^6 to about 5–6 × 10^5 (this phase showed all the features already described for the degradation of DNA by the crude enzymic preparation); (2) a second phase in which the molecular weight continued to drop at a slower rate. In this phase, which had not been detected when using the crude enzyme, there was formation of acid-soluble nucleotides and an increase in the ultra-violet absorption coefficient at 260 mμ. A calf thymus acid deoxyribonuclease (DNase) preparation, to be described elsewhere[6], degraded DNA in much the same way as the purified chicken erythrocytes preparation and was used almost exclusively in further work.

As our previous results[1,2] strongly suggested, a non-random breakdown of DNA by the enzyme, and as a similar suggestion had been put forward by Oth *et al.*[7] in their work on the degradation of DNA by acid DNase, the kinetics of the enzymic degradation was investigated in detail. Digestions were carried out in the light-scattering cell at 20°; to 30 ml. of 5–10 mgm./100 ml. of DNA (molecular weight = 6×10^6) in acetate buffer $pH = 5·4$, $\mu = 0·15$, 0·02 ml. of the enzymic preparation (generally containing 10γ protein) was added and molecular weights were determined at intervals of time. No time-lag was detectable, and the initial slope of log $(1 - R)$ versus log t ($R = M_w/M_w^0$; M_w = weight average molecular weight; M_w^0 = initial molecular weight; t = time) was near to 1. Therefore, making the reasonable assumption that $p_t = kt$ (p_t being the probability that any given bond will be cleaved during time t, and k a constant) for values of R between 1 and 0·8, it is concluded that the degradation occurs according to a 'single strand' degradation kinetics[8]. The same behaviour was displayed by DNA samples obtained by enzymic action and ranging in molecular weight from 6 to $1·1 \times 10^6$.

The degradation of DNA 'sub-units' was studied next. Several samples, obtained by enzymic action from different DNA preparations, and exhibiting molecular weights between 7 and 9 × 10^5 (in acetate buffer $pH = 5·4$, $\mu = 0·15$), were deproteinized by shaking with chloroform *iso*amyl alcohol and then digested in the light-scattering cells as before (DNA concentrations were 10–20 mgm./100 ml.). A time-lag was evident and the initial slope of log $(1 - R)$ versus log t was close to 2. Therefore, making the same assumptions as before, degradation occurred according to a 'double strand' kinetics.

Finally, the transition phase between the two degradation kinetics was investigated; as expected, this was characterized by a plateau region, in which the molecular weight did not change.

These results show that two different types of degradation are going on at the same time. The 'single strand' degradation is the only one apparent in the first phase, because it is acting during the time-lag of the 'double strand' degradation. Whereas the latter is a random degradation of the type already known for neutral DNase[8,9], the 'single strand' degradation as shown by this work is highly specific and unequivocally shows that (1) sites exist in DNA ($M_w = 6 \times 10^6$) where the enzymic action brings about the splitting of the molecule without any time-lag and (2) the number of these sites is discrete.

Relative Sweetness of α- and β-Forms of Selected Sugars

THE mechanism of taste perception has been approached through work on the relationships between chemical properties of taste stimuli and their resultant taste responses. Ferguson and Lawrence[1,2] reported that the D-configurations of leucine, *iso*leucine, valine, histidine, tryptophan and asparagine were sweet, whereas the L-forms were not. These authors observed that *iso*maltose (6-α-D-glucopyranosyl-D-glucose) was sweet, but its anomer, gentiobiose (6 - β - D - glucopyranosyl - D - glucose), was bitter. Cameron[3,4] found that a freshly prepared solution of 10 per cent α-D-glucose was definitely sweeter than a 16-hr.-old 10 per cent solution. The magnitude of the response (fourteen evaluations) suggested that the fresh solution had a sweetness equal to or more than that of a 10·5 per cent equilibrium solution.

The investigation discussed here was designed to repeat Cameron's work and to determine whether the α- and β-forms of other sugars differ in relative sweetness. The mutarotation-rates at room temperature of glucose, fructose, galactose, and lactose were determined by polarimetric measurements. Equilibrium between the α- and β-forms of these sugars was attained within 2·5 hr. after hydration. Consequently, to ensure having an equilibrium mixture, sugars were hydrated 3 hr. before tasting. Before this experiment, it was established that a freshly hydrated solution of sucrose, which does not undergo mutarotation, did not differ in sweetness from a 16-hr.-old solution.

The taste panel consisted of two women and three men, selected on the basis of their high acuity for detecting sweetness differences from an original group of eleven experienced tasters. Evaluations were made daily at 11.30 a.m. in individual, partitioned booths maintained at a controlled temperature. At each session every judge received four pairs of solutions, one of each pair having been hydrated 3 hr. previously, the other hydrated 100–200 sec. before tasting. The time between hydration of the fresh sample and tasting was kept to a minimum by adding freshly distilled water to the weighed compounds in individual volumetric flasks as each judge entered the booth. Judges were requested to circle the number of the sample within each pair which had the greater sweetness. The order of sample presentation was randomized. Distilled water was provided for oral rinsing at the judge's discretion. A minimum of forty separate evaluations per pair was collected. The method in ref. 5 was used to establish significant differences.

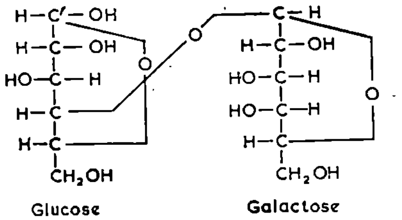

Fig. 1. α-Lactose (D-glucose-4(β-D-galactopyranoside))

As shown in Table 1, the differences in sweetness between the α- and β-configurations became greater as the concentration of the sugar increased. The α-configurations of fructose, glucose and galactose were sweeter than the β-forms, whereas the reverse was true for lactose. This observation is of interest, since the same asymmetric carbon atom (C–1) is responsible for the specific rotation of the lactose molecule as for the glucose molecule (Fig. 1). Rogers[6] suggested that the greater solubility of β-lactose ($55^{20^\circ\text{C.}}$ in 100 parts water) as compared with the α-form ($8^{20^\circ\text{C.}}$)[7] contributed to its greater sweetness. However, β-D-glucose is more soluble but less sweet than α-D-glucose ($154^{15^\circ\text{C.}}$, $82^{25^\circ\text{C.}}$, respectively)[8]. When 10 per cent α-D-glucose was used as a sweetener in peach nectar, 76 per cent of 66 comparisons showed

Table 1. RELATIVE SWEETNESS OF α- AND β-FORMS OF FOUR SUGARS

Compound	Concentration (per cent)	No. of evaluations	Sec. after hydration	Response considering (per cent)

the freshly sweetened nectar to be sweeter than that sweetened 6 hr. before.

In extensive work on the effectiveness of various carbohydrates in stimulating labellar and tarsal hairs of the blowfly, *Phormia regina*, Dethier[9] observed no significant differences in thresholds between α-D-glucose and an equilibrium mixture. On the other hand, Dethier demonstrated a difference between α-nitroglucose and β-nitroglucose, the former being somewhat more effective. The most striking difference was found in the great effectiveness of α-methyl glucoside in contrast to the ineffectiveness of β-methyl glucoside. The most effective carbohydrate stimuli for *Phormia regina* included compound sugars with an α-D-glucopyranoside link. Enzyme inhibitors such as azide, iodoacetate, phlorizin and fluoride did not prevent stimulation.

In his review on the relationship between molecular structure and odour, Stoll[10] stated that if optical isomers are distinguishable by their odour, molecules constituting the receptors may be optically active also, and thus exhibit a different adsorbent activity towards the odorous molecules in contact with them according to the sign of rotation of the latter. Lawrence and Ferguson[2] tested the theory that the stereospecific surface of the taste organ might be that of an enzyme, by measuring the adsorption of sweet and non-sweet isomeric pairs of compounds on charcoal, cut human hair, and tongue surfaces. No significant differences in adsorption were observed. In addition, these investigators found no obliteration of the sweet taste in the presence of the enzyme inhibitors, sodium azide, potassium fluoride, sodium iodoacetate, and sodium cyanide. Baradi and Bourne[11,12] reported that in the papilla foliata of the rabbit, quinine inhibited glycerophosphatase, 5-nucleotidase and esterase reactions, and greatly increased the ribonuclease reaction. Sucrose had no effect and saccharine inhibited esterase.

It must be concluded that the reason for differences in sweetness evoked by anomers of various compounds remains to be elucidated. The results reported here confirm Cameron's observations on glucose[3] and establish that the anomers of fructose, galactose, and lactose differ in intensity of sweetness also. Consequently, to assure equilibration of the α- and β-forms, sweetness investigations of asymmetrical sugars should involve hydration several hours before tasting.

BIOPHYSICS

The Action Potential in Cells of *Chara*

IN the resting state of giant internodal cells of the fresh water algæ, *Chara* and *Nitella*, an electric potential difference exists between the interior of the cells and an external medium. The value of this potential difference appears to be determined by the permeability of the plasmalemma (outer cytoplasmic membrane) to potassium ions and, to a lesser extent, to sodium ions[1,2]. The resting resistance of this membrane is also related to the permeability to these ions and to their external concentrations[2].

The action potential, which is a reversible depolarization of the plasmalemma[3], occurs on stimulation of the cells by a pulse of current or by abrupt change in temperature, etc. It might be suggested that the action potential in the Characeae, which is qualitatively similar to the conducted impulse in a nerve axon, is similarly related to quick changes in permeability of the cell.

Osterhout[4] proposed a mechanism involving potassium ions and the inner cytoplasmic membrane (tonoplast), but this seems unlikely since, in fact, the action potential occurs across the plasmalemma and the potassium ion is almost in electrochemical equilibrium across it. Thus the potential difference would not be expected to change greatly if a change towards increased permeability to potassium occurred.

Gaffey and Mullins[5] reported that increased fluxes of potassium and chloride accompanied the action potential in cells of the corticated species *Chara globularis* and that the potential difference at the peak of the action potential was influenced by the concentration of chloride in the external medium.

The present investigation is concerned with the effects of changes in concentration of various ions on the action potential in single cells of *Chara australis*. An alternative explanation of some of the results of Gaffey and Mullins is offered.

Continuous records on a chart recorder were made of the potential difference between a micro-electrode in the vacuole and an external medium. A second electrode in the vacuole was used to pass current pulses to initiate action potentials. The threshold was generally about 30 mV. above the resting level. To investigate the effect of changes in concentration of a particular ion, the total concentration was kept constant and the concentration of one ion species varied at the expense of another, so that the cell wall potential remained constant[2].

Fig. 1 shows the resting potential difference and the potential difference reached at the peak of the action potential, as functions of calcium concentration, $[\mathrm{Ca}^{++}]_0$, in solutions of calcium and magnesium chloride of total concentration 6 m*N*. All solutions also contained 1 m*N* sodium chloride and 0·1 m*N* potassium chloride. While the resting potential was almost unaffected by changes in concentration of calcium or magnesium, the peak of the action potential was changed reversibly, a new value being reached within about 10 min. of changing the concentration. It is seen that the peak of the action potential approximately follows a line with a slope of 29 mV./(10 × $[\mathrm{Ca}^{++}]_0$), but with a tendency (observed in several experiments) for the peak to be more negative than the extrapolation of this line at low calcium concentration.

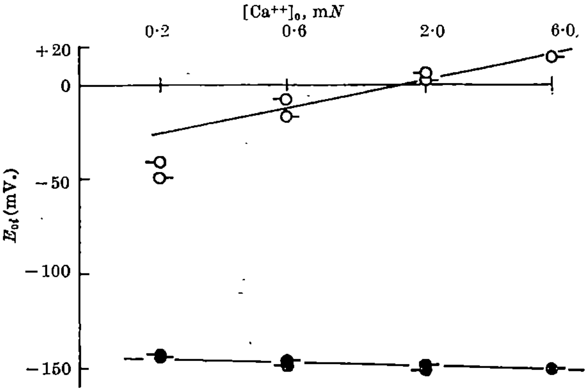

Fig. 1. Resting potential (●) and peak level of the action potential (○), plotted against calcium concentration on a logarithmic scale

Bars on the symbols show direction of increasing or decreasing concentration, starting and finishing at 0·2 m*N*. The line through some of the points for action potential has a slope of 29 mV. per ten-fold change in external calcium concentration

In the presence of calcium ions, changes in concentration of other ion species had no consistent effect on the peak of the action potential. In the absence of added calcium ions, the peak did not hold a steady value, but became more negative with time as a consequence of the removal by cation exchange via the cell wall Donnan phase[2] of the calcium in the immediate neighbourhood of the plasmalemma. Fig. 2 shows the decline in the magnitude ΔE of the action potential (the change in potential from resting-level to peak) in solutions of choline chloride. The rate of decrease of ΔE was greater in 10 m*N* than in 3·3 m*N* choline chloride. This agrees qualitatively with comparative rates of exchange in isolated cell walls of *Chara*[6].

In solutions not containing calcium, the cell eventually reached a stage where it could not be stimulated by pulses depolarizing the cell by as much as 100 mV.

It is now suggested that, had the changes in the experiments of Gaffey and Mullins[5] been made in the direction of increasing choline chloride concentration, the magnitude of the action potential would have appeared to decrease with increasing concentration of chloride (Fig. 3 in Gaffey and Mullins[5]), whereas in fact the decrease was a function of time. However, the reported extra fluxes of chloride during the action potential in *Chara globularis* remain unexplained.

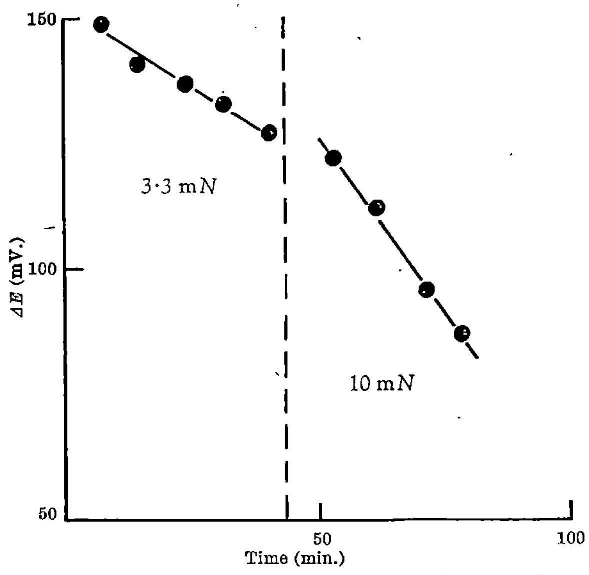

Fig. 2. The magnitude (ΔE) of the action potential in a cell in 3·3 m*N* and 10 m*N* choline chloride, plotted against time

The change in concentration of choline chloride was made at the time indicated by the dotted line

In the present experiments the action potential may be described in terms of a sudden increased permeability of the plasmalemma to calcium such that the potential approaches the ion equilibrium potential for this ion, given by:

$$E_{0i} = \frac{RT}{2F} \ln ([\mathrm{Ca}^{++}]_0/[\mathrm{Ca}^{++}]_i) \qquad (1)$$

$$= \text{const.} + 29 \log_{10} [\mathrm{Ca}^{++}]_0 \text{ at } 19^\circ \text{ C.} \qquad (2)$$

The effect of calcium was obtained in the presence of concomitant changes in magnesium, barium, or strontium concentration and is therefore specific to calcium. Changes in permeability to other ions besides calcium may be involved in the action potential. This may explain some observed deviations from the relation predicted by equation (1) or (2).

Voltage-Clamp Experiments with *Nitella*

HOPE[1] has suggested that in the large internodal cells of *Chara australis*, the depolarization of the plasmalemma during an action potential is caused by a sudden transient increase in the permeability of this membrane to calcium ions, and a consequent inward movement of these ions. This suggestion followed from an investigation of the effects of changes in concentration of various ions on the action potential in single *Chara* cells.

Recently, in this laboratory, it has been possible to examine in more detail the action potential process by applying a 'voltage-clamp' technique to the ecorticate internodal cells of a species of *Nitella*. The action potential in these cells has been described previously by Findlay[2]. In the voltage-clamping method a feed-back circuit is used to change the membrane potential to some pre-determined level and maintain it as close as possible to this level during the electrical activity of the cell. The current flowing across the membrane during the voltage-clamp is recorded. Fig. 1 shows the relationship between membrane current and time, for different membrane potentials. It is seen that the current may be divided into two components: a transient inward current and a steady outward current.

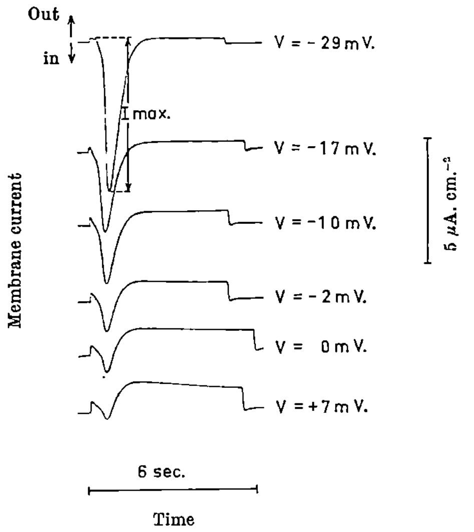

Fig. 1. Records of membrane current under a voltage-clamp. The membrane potential is shown at the right of each curve. The maximum inward current is shown as $I_{\text{max.}}$

Whereas the outward current increases as the membrane potential is changed in the positive direction, the inward current decreases, and eventually becomes zero.

The effect of external calcium concentration on these currents was investigated. The membrane potential – maximum inward current relationship for different concentrations of external calcium, $[\text{Ca}^{++}]_{\text{ext.}}$, was determined. It was also found that $[\text{Ca}^{++}]_{\text{ext.}}$ had little effect on the steady, outward-flowing current. Some results are shown in Fig. 2*a*. In this experiment, the cell was bathed in a solution of calcium and magnesium chloride and the calcium concentration varied at the expense of the magnesium. The total ionic concentration of the solution was kept constant throughout the experiment to eliminate changes in potential difference across the cell wall Donnan system[3]. In Fig. 2*b* the membrane potential for which the inward current was zero and the potential at the peak of an ordinary action potential are plotted against $[\text{Ca}^{++}]_{\text{ext.}}$

The role of the chloride in the action process was examined by determining the relationship between the clamped potential (V) and the maximum inward current ($I_{\text{max.}}$) for different $[\text{Cl}^{-}]_{\text{ext.}}$ and fixed $[\text{Ca}^{++}]_{\text{ext.}}$. The results are shown in Fig. 3. Curves (*a*) were obtained with $[\text{Ca}^{++}]_{\text{ext.}} = 0{\cdot}1$ mN and $[\text{Cl}^{-}]_{\text{ext.}} = 0{\cdot}1, 0{\cdot}3, 1{\cdot}0$ mN, and curves (*b*) with $[\text{Ca}^{++}]_{\text{ext.}} = 1{\cdot}0$ mN. The three curves in each of the two groups lie close to one another, and intersect the membrane potential axis at approximately the same position.

The results summarized in Fig. 2 show that the membrane potential for which the initial inward current is zero depends on $[\text{Ca}^{++}]_{\text{ext.}}$. The slope of the $V/I_{\text{max.}}$ curve, a measure of the minimum resistance of the membrane during activity, is of the order of 2–4 k.Ωcm.^{2}, while the resting resistance of the *Nitella* membrane is 30–80 k.Ωcm.^{2}. Fig. 3 shows that $[\text{Cl}^{-}]_{\text{ext.}}$, however, has little effect on the $V/I_{\text{max.}}$ relationship. These results indicate that the plasmalemma of *Nitella* during the initial stage of the action potential undergoes a transient increase in permeability to calcium. During this time calcium controls the $V/I_{\text{max.}}$ relationship. Hence, the membrane potential for which the calcium current is zero is the electrochemical equilibrium potential for calcium. Consequently, if $[\text{Ca}^{++}]_{\text{ext.}}$ is changed the intercept of the $V/I_{\text{max.}}$ graph with the V axis should vary according to the Nernst equation, namely a change of 29 mV. for each ten-fold change in $[\text{Ca}^{++}]_{\text{ext.}}$. However, it is found that in *Nitella* the change is usually 35–40 mV. One possible explanation of this larger value is that calcium is partly in the form of a monovalent complex, and both this and the divalent calcium together control the action potential. The 35–40 mV. change for ten-fold change in $[\text{Ca}^{++}]_{\text{ext.}}$ would represent the combined behaviour of the two forms of calcium. A plot of the potential at the top of the

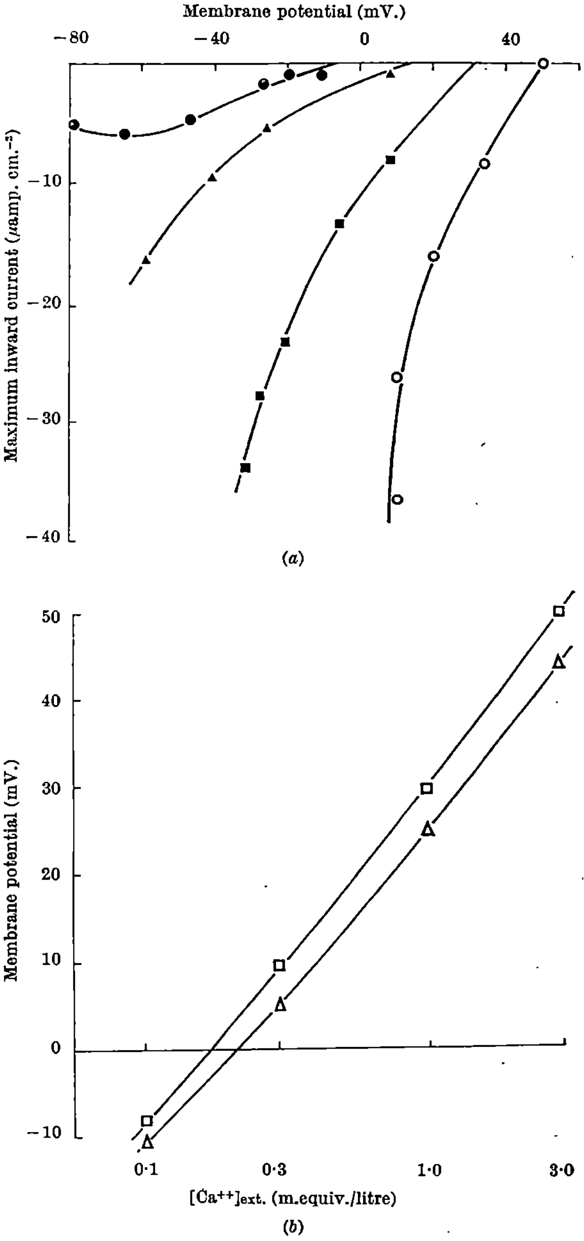

Fig. 2. (*a*) Relationship between maximum inward current and membrane potential for different $[\text{Ca}^{++}]_{\text{ext.}}$ ●, 0·1 mN; ▲, 0·3 mN; ■, 1·0 mN; ○, 3·0 mN. (*b*) Relationship between $[\text{Ca}^{++}]_{\text{ext.}}$ and membrane potential for $I_{\text{max.}} = 0$ (□), and potential at peak of ordinary action potential (△)

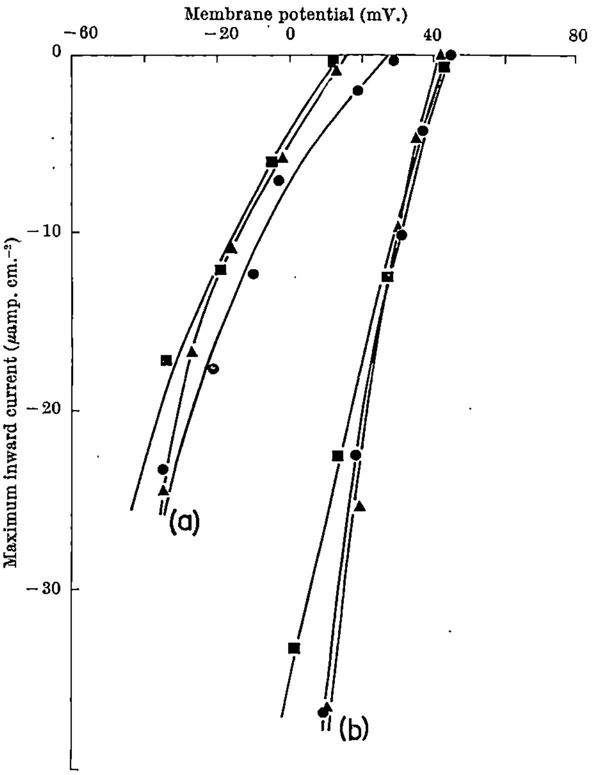

Fig. 3. Relationship between maximum inward current and membrane potential for varying $[Cl^-]_{ext.}$, and $[Ca^{++}]_{ext.}$ Curves (*a*) 0·1 m*N*; curves (*b*) 1·0 m*N* $[Ca^{++}]_{ext.}$ with $[Cl^-]_{ext.}$ = 0·1 (●); 0·3 (▲), and 1·0 (■) m*N*

spike of an ordinary action potential against $[Ca^{++}]_{ext.}$ also has a slope of 35–40 mV. per tenfold change in $[Ca^{++}]_{ext.}$. Furthermore, it is possible, as Hope[1] suggests, that other ions besides calcium may be involved to some extent in the action potential, and that the peak potential is not the electrochemical equilibrium potential for calcium alone.

Further evidence for an increase in membrane permeability to calcium during activity is afforded by the result that for any one membrane potential-level the maximum inward current increases as $[Ca^{++}]_{ext.}$ increases. This is not the case with chloride.

The foregoing experiments thus substantiate Hope's[1] conclusion that the calcium ion plays a major part in the action potential process. The voltage-clamp results show that the action potential (initiated when the membrane potential is raised above the threshold) results from a transient increase in membrane permeability to calcium. The membrane potential changes towards the electrochemical equilibrium potential for calcium. However, before this potential-level is reached (see Fig. 2*b*), the calcium permeability has decreased, and the membrane potential returns to the resting-level. The recovery is probably the result of an outward movement of potassium ions.

PHYSIOLOGY

Spontaneous Miniature Potentials from Insect Muscle Fibres

Recent reports[1,2] describe spontaneous potential changes at crustacean neuromuscular junctions which bear a close resemblance to vertebrate miniature endplate potentials[3]. Quantal 'packets' of acetylcholine, released from the pre-synaptic terminals of the vertebrate motor nerve, produce transient depolarizations at the post-synaptic muscle membrane of about 0·5 mV. Since reports of a similar type of activity at the insect neuromuscular junction have so far been lacking, it appeared of interest to submit the following account of its occurrence in this group.

Randomly occurring spontaneous potentials of up to 1 mV. have been recorded, in the giant South American cockroach, *Blaberus giganteus*, from single muscle fibres of the extensor tibiæ using internal micro-electrodes of resistance between 10 and 20 M.ohm. Considerable variations were observed (Fig. 1) in both amplitudes and rise times. These findings are consistent with the multi-terminal nerve innervation known to be present in insects[4,5]. The similarity of these transients to the spontaneous phenomena exhibited by the 'slow' fibres of the frog[6] is very evident. It is possible to visualize a series of junctions displaced along the muscle fibre, discharging randomly to produce a variety of potential types at the recording site.

Values for discharge frequencies collected from fibres of a large number of specimens followed a normal distribution curve ranging from 1 per sec. to 15 per sec. In general, the values were rather higher than those recorded for either the frog or the crayfish, and it is possible that the saline used[7] was slightly hypertonic to the body fluids. An increase in tonicity leads to a rise in the rate of discharge. For example, when the normal saline was replaced with one made five times hypertonic with sucrose, a marked increase in the frequency occurred over the first minute after application, followed by a gradual decline to zero over the next 30 min. Following return of the preparation to fresh normal saline, the normal discharge frequency returned (Fig. 2).

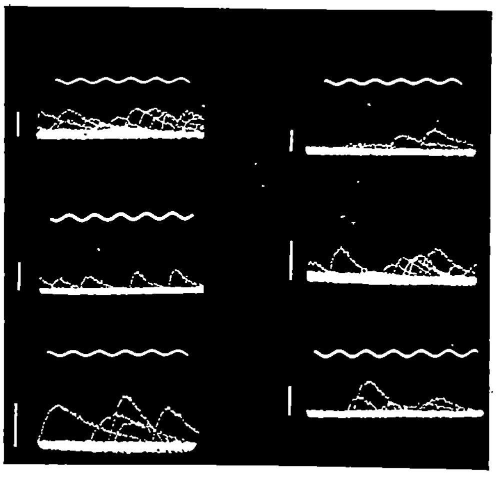

Fig. 1. Spontaneous potentials from six different muscle fibres of *Blaberus giganteus* with intracellular recording. Note variations in amplitudes and time-courses of potentials. Records were obtained by superimposition of a number of traces for each fibre. Vertical calibrations equal to 1 mV. Time calibrations, 400 c./sec.

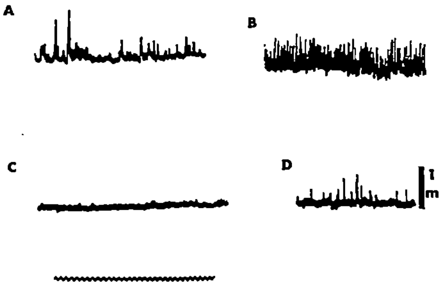

Fig. 2. Effect of tonicity on amplitude and frequency of spontaneous potentials. (*A*) Normal saline; (*B*) effect after 1 min. of increasing tonicity by a factor of five through the addition of sucrose to the saline; (*C*) effect after 30 min.; (*D*) return to normal tonicity. Voltage calibration same for *A*, *B*, *C* and *D*. Time calibration same for *A*, *B*, *C* and *D* at 30 c./sec.

A few recordings from the metathoracic extensor tibiae muscle fibres of the locust *Schistocerca gregaria* followed closely the pattern described for *Blaberus giganteus*.

It seems possible that the quantal transmitter discharge characteristic of the vertebrate nerve ending is also to be found in the insects, although the chemical identity of the transmitter substance is not yet known for any insect neuromuscular junctions.

Thermodynamics and Osmoregulation

During a recent meeting concerning renal function one of the speakers suggested that the reason for the high metabolic rate of the mammalian kidney might be further investigated since very little energy seems to be used in forming the urine. The allusion was to a computation by Borsook and Winegarten[1] showing that the thermodynamic efficiency of the kidney is about 1 per cent. However, the inference, encountered not infrequently, and not only in connexion with renal function, is based on a misunderstanding of the nature of the computation.

The thermodynamic work performed by an organ like the kidney is the sum of a sequence of terms $RT \ln \frac{[a]\text{ blood}}{[a]\text{ urine}}$ for each of the components of the urine. Here $[a]$ is the activity of the substance, usually approximated by its concentration. It is important to note that this value depends solely on the initial and final states of the system (for example, blood and urine concentrations of the constituents), and on the temperature. It is completely independent of the mechanism by which the urine is formed. The actual energy expended by an organ like the kidney is a function of these mechanisms, and it is this parameter, and not the thermodynamic work done, that is reflected in the oxygen consumption of the organ. To return to the case of the mammalian kidney, if we take account of the manner in which the urine is formed, and use some recently published results on the energetics of sodium transport, it is easy to show that there is no mystery about the high oxygen requirement of this organ. It has been shown that about 16 equivalents of sodium ion are transported across the frog skin per mole of oxygen used[2,3]. In the course of a day the human kidneys filter about 30 equivalents of sodium, nearly all of which is re-absorbed. If we assume that all the re-absorption requires energy, and use Zerahn's value for sodium/oxygen (thereby assuming that the renal 'sodium pump' is the same as that in the skin of the frog) the rate of oxygen consumption would be about 25 ml./min. This is actually slightly higher than the total oxygen consumption for the organs, and no account has been taken of energy expended in re-absorbing other solutes. It is possible that some sodium is re-absorbed by systems with a lower energy requirement (for example, by forced exchange against H^+ and NH_4^+), or that sodium/oxygen < 16. The reasonable correspondence between observed and computed values, however, makes it obvious that a large fraction of the energy turnover must be devoted to solute re-absorption.

This type of misconception is not restricted to discussions on the mammalian kidney. Schlieper[4] has summarized much evidence showing that the oxygen consumption of aquatic organisms increases as their environment becomes more dilute. These data have been interpreted to mean that increased work is being done by the osmoregulatory organs in dilute media. This interpretation has been criticized, and one of the major objections has been based on the same misuse of the thermodynamic argument. Potts[5] has shown that the thermodynamic work done by the gills and kidneys of these organisms represents a very small proportion of their total energy turnover. Potts's data have been used as the basis for the argument that increased activity of the osmoregulatory organs could not account for the rise in oxygen consumption, which is often as large as 20–40 per cent[6,7]. As in the previous case the computation concerns thermodynamic work and is a minimal, not a realized value. The actual energy expended by the osmoregulatory organs depends on the mode of their operation; not on the initial and final states, but on the path by which the transformation is made. Thus, oxygen consumption of the crayfish antennal gland is about 5 per cent of the animal's total[8], certainly not a negligible fraction. If this organ, like the vertebrate kidney, functions on a filtration–re-absorption basis[9], it is likely that cessation of urine formation alone would cause a measurable fall in basal oxygen utilization. Such a cessation has been noted when the osmotic concentration of the external environment is raised. In addition, blood sodium rises when the concentration in the environment is increased. Since the rate of sodium uptake by the gills varies inversely with blood sodium-level[11], energy expenditure by the gills might also be expected to decrease in brackish water. The result would be just that noted by Schlieper: lower energy expenditure in the more concentrated medium. Thus, if the mechanisms are considered, an appreciable change in resting oxygen consumption is not only reasonable, but might have been predicted. However, it is not the chief purpose of this communication to defend Schlieper's thesis, but to point out that the thermodynamic argument against it is not valid.

While the thermodynamic work performed sets no upper limit on the amount of energy that may be expended it does provide an absolute minimum. Thus it is useful in evaluating models that are proposed for solute and solvent transport. In addition, use of a thermodynamic approach to osmoregulation has led to some interesting speculation about the evolution of these systems. If this approach is to be fruitful, however, the limitations of thermodynamics have to be observed.

Effects of Drugs on Uptake of Isotopic Norepinephrine by Cat Tissues

PREVIOUS experiments have shown that catecholamines enter tissue slices both by simple diffusion and by a concentrating mechanism that can be demonstrated in brain, heart and spleen, but not in muscle or liver, when these tissues are incubated with physiological concentrations of isotopic epinephrine or norepinephrine[1,2]. The uptake by the concentrating mechanism is maximal in media containing 10–25 mμgm. of norepinephrine per ml. and is inhibited by reserpine and ouabain. At concentrations of norepinephrine greater than 200 mμgm. per ml., uptake by the concentrating mechanism becomes negligible in comparison to the amount entering by diffusion and the effect of reserpine is no longer demonstrable.

The present experiments were undertaken in the hope that the effects of several drugs on the uptake of norepinephrine may be related to their pharmacological effects. Slices of cat tissue were incubated for 45 min. in Krebs bicarbonate medium containing the appropriate drug and 5 mμgm. of *dl*-norepinephrine-7^{3}H per ml. The concentration of radioactivity in control slices of cortex, heart or spleen incubated without drug was usually about four times that in the medium. Approximately 80 per cent of the total radioactivity in the slices after incubation was accounted for chromatographically[3] as unchanged norepinephrine. The effects of a number of drugs on the uptake by the concentrating mechanism are listed in Table 1. In these experiments diffusion alone may be expected to give concentrations of norepinephrine in tissue approximately equal to that in the medium[2]. Percentage inhibition of the concentrating mechanism is therefore expressed as 100 × $(C_C – C_D)/(C_C – C_M)$, where C_C and C_D are the concentrations of isotopic norepinephrine in the tissue of the control and drug-treated slices respectively and C_M is the concentration in the incubation medium.

Table 1. EFFECT OF DRUGS ON THE CONCENTRATION OF RADIOACTIVITY IN SLICES OF CAT TISSUE INCUBATED 45 MIN. WITH *dl*-NOREPINEPHRINE-7^{3}H (5 MμGM./ML.)

Norepinephrine uptake in heart slices was used for a comparison of the inhibitory effects of equimolar concentrations of several alkaloids structurally related to reserpine. The sedative agents, reserpine, recanescine and rescinnamine, were effective inhibitors. It is noteworthy that isoreserpine, which is without effect on uptake of norepinephrine, differs from reserpine only in the configuration at one carbon atom.

Both sympathomimetic and sympatholytic drugs are among the substances that inhibit the uptake of norepinephrine. Some of the former, including tyramine, ephedrine and amphetamine[4], may exert their effects by displacing norepinephrine from tissue stores near sympathetic nerve endings, thus making the amine available to receptor sites. The structural similarity of these amines to norepinephrine suggests that the displacement may result from competition by these agents for tissue storage sites.

Other inhibitory agents also release catecholamines from tissues, presumably by other mechanisms. The depletion of catecholamines by reserpine[5–7], for example, may result from some slowly reversible change in cell structure, since the effects of this drug persist for so long a time after its disappearance from the body. Guanethidine is unusual in that it depletes peripheral tissues of norepinephrine, but not of 5-hydroxytryptamine (5HT) (ref. 8). Experiments with blood platelets indicate that depletion of 5HT may result from interference by reserpine with an active transport mechanism that helps to maintain high intracellular levels of the former[9]. Depletion of norepinephrine stores in cells may be related to the effect of reserpine-like drugs on the uptake mechanism reported here.

The property most commonly encountered among these inhibitory drugs is the enhancement of the response of adrenergic organs to norepinephrine administered. This occurs with cocaine[10], reserpine[11], and bretylium[12] as well as with some sympathomimetic amines[5]. Sensitization can be demonstrated with chlorpromazine[13]. Thyroxine, which has been found in a separate investigation to block the uptake of norepinephrine (Dengler, H. J., unpublished results), is also a potentiator.

The uptake mechanism may well be a means for terminating the biological response to catecholamines by removing them from the site of activity. Should this be so, sensitization by these drugs would be expected as a consequence of their inhibitory properties. Evidence for the termination of biological effect by some sort of intracellular re-distribution rather than by metabolic alteration of the catecholamines has been reviewed recently[14].

Stimulation by Aldosterone of Sodium Transport in the Loop of Henle

Jones and de Wardener[1] have reported that normal subjects, when hydropenic, excrete a urine osmotically more concentrated than when given large quantities of vasopressin while hydrated. During dehydration, one element coming normally into play, besides antidiuretic hormone, is a hypersecretion of aldosterone by the adrenal cortex, as a response to the shrinkage of the liquid compartments of the body[2,3]. The possible influence of aldosterone on the concentrating capacities of the human kidney was therefore evaluated by comparing the urinary osmotic pressure after administration to hydrated subjects of vasopressin alone and of vasopressin associated with aldosterone.

Seven tests were performed on five normal young males. Two and a half units of 'Pitressin' tannate were injected subcutaneously at 8 a.m., first alone, then, one week later, in association with 0·5 mgm. of D-aldosterone-21-monoacetate in oil. The subjects emptied their bladders 2 hr. after the injections, and collected urine thereafter for a period of 8 hr. during which they were asked to drink about 1 litre of fluids in addition to their usual diet. The urine osmolality (m.osm./kgm. water) was determined with a Fiske osmometer.

The results are presented in Table 1. In the presence of aldosterone, there was a larger increase in urine osmotic pressure after injection of vasopressin.

The mean urine osmolality figure of 955 obtained after administration of vasopressin alone is comparable with the mean value of 972 reported by Jones and de Wardener, who indeed pointed out that the dose of 2·5 units of vasopressin sufficed to produce a maximal effect on the urinary osmotic pressure of their hydrated normal subjects.

Table 1. URINE OSMOLALITY IN NORMAL HYDRATED MALES AFTER VASOPRESSIN ASSOCIATED WITH OR WITHOUT ALDOSTERONE

If aldosterone improves the concentrating ability of the human kidney, the conclusion may be drawn that this hormone stimulates the re-absorption of sodium (chloride) in the ascending limb of the loop of Henle. Sodium transport at that site, from the tubular lumen to the interstitium, is taken as the prime mover in the operation of the counter-current concentrating mechanism of the renal papilla[4,5]. Factors exerting an effect on the rate of sodium transport at that level would in turn influence the efficiency of the whole process of urine concentration. As suggested by the results presented here, aldosterone is one of these factors. They indicate, furthermore, that, even when stimulated by aldosterone, sodium transport in that part of the nephron is not linked to the secretion into the urine of other cations. It is pertinent to mention here that aldosterone has recently been shown to enhance active sodium transport in the isolated urinary bladder of the toad[6], a preparation in which sodium (chloride) movement is not coupled with cationic secretion[7].

I wish to express my gratitude to Mr. P. Denis, Parke, Davis and Co., for the gift of 'Pitressin' tannate, and to Prof. R. Gross, Ciba A. G., Basle, for the gift of D-aldosterone-21-monoacetate.

PHARMACOLOGY

Inhibition of Phosphorylation by Atractyloside

IN previous papers it was shown that atractyloside, a glycoside (formerly called K-atractylate) extracted from the rhizome of *Atractylis gummifera*, the aglycone of which contains the perhydrophenanthrene nucleus[1], inhibits the uptake of oxygen by rat-liver mitochondria also at very low concentrations (0·0000036 *M*) and with a marked decrease of the P/O ratio[2].

Using hypotonically treated rat-liver mitochondria, with reduced diphosphopyridine nucleotide or ferrocytochrome-*c* as substrates, inhibition of phosphorylation was observed without decrease in the rate of oxygen uptake[3]. The 2,4-dinitrophenol-induced adenosine triphosphatase of intact mitochondria was inhibited by this drug, but the same was not true for Mg^{++}-activated adenosine triphosphatase of mitochondria disrupted by deoxycholate[4].

In this communication evidence is presented that inhibition of mitochondrial respiration by atractyloside might be due exclusively to interference with phosphorylation reactions.

Table 1 shows that : (*a*) atractyloside has no effect on the oxygen uptake of water pre-treated mitochondria oxidizing β-hydroxybutyrate ; (*b*) atractyloside fails to produce inhibition of respiration in an adenosine triphosphate-, glucose- and hexokinase-deficient system and in a phosphorus-deficient system; (*c*) the respiration of mitochondria, observed under phosphorylative conditions in the presence of atractyloside, is very similar to that of mitochondria incubated in the absence of adenosine triphosphate (ATP), glucose and hexokinase; this fact could indicate that the increase of uptake of oxygen due to phosphorylation is inhibited by the drug. Phosphorus was estimated by the Fiske and Subbarow method and a complete block of phosphorus uptake was observed in the vessels containing atractyloside.

Table 1. EFFECT OF ATRACTYLOSIDE ON MITOCHONDRIAL RESPIRATION
The oxygen uptake was measured manometrically at 26° C. in the Warburg apparatus. The vessels contained: (*a*) 0·03 *M* potassium phosphate buffer, *p*H 7·4, 0·005 *M* $MgSO_4$, 0·00036 *M* diphosphopyridine nucleotide, 0·001 *M* ethylenediamine tetraacetate, 0·09 *M* sucrose, 0·02 *M* β-hydroxybutyrate, 1 mgm. of nitrogen rat-liver mitochondria (isolated in 0·25 *M* sucrose and pre-treated with water for 30 min. at 0° C). (*b*) 0·015 *M* potassium phosphate buffer, *p*H 7·4, 0·03 *M tris* buffer, *p*H 7·4, 0·005 *M* $MgSO_4$, 0·03 *M* glucose, 0·0014 *M* ATP, 0·8 mgm. yeast hexokinase (Sigma type II), 0·01 *M* glutamate (or 0·02 *M* β-hydroxybutyrate), 0·001 *M* ethylenediamine tetraacetate, 0·09 *M* sucrose, 0·000005 *M* cytochrome-*C*, 1 mgm. of nitrogen rat-liver mitochondria (isolated in 0·25 *M* sucrose). Final volume, 2·8 ml.; time of incubation, 20 min.; exceptions are indicated; gas-phase, air; KOH and filter paper in the centre well. Inorganic phosphate was omitted by the Borst and Slater (ref. 5) procedure; P/O ratios are reported in parentheses.

Substrate	Omissions	Oxygen uptake (μatoms)	
		Without atractyloside	Atractyloside 0·00005 *M*
(*a*) Water pre-treated mitochondria			
β-Hydroxybutyrate	Nil	5·8	5·8
(*b*) 0·25 *M* sucrose mitochondria			
β-Hydroxybutyrate*	Nil	2·9 (2·6)	1·2 (0)
β-Hydroxybutyrate*	ATP, glucose, hexokinase	1·2	1·2
β-Hydroxybutyrate*	inorganic phosphate	1·1	1·1

Glutamate	inorganic phosphate	1·4	1·3

* Time of incubation 10 min.

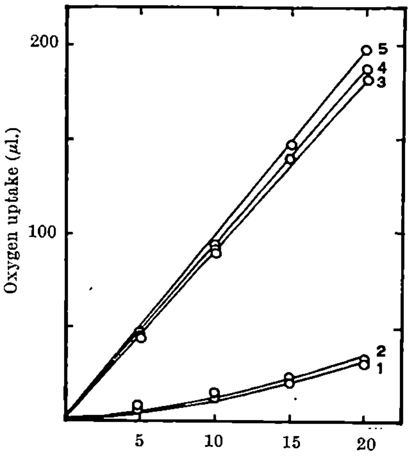

Fig. 1. The effect of atractyloside on the rate of glutamate oxidation under phosphorylative conditions and in presence of 2,4-dinitrophenol. The vessels contained 0·015 *M* potassium phosphate buffer, *p*H 7·4, 0·03 *M tris* buffer, *p*H 7·4, 0·005 *M* $MgSO_4$, 0·001 *M* ethylenediamine tetraacetate, 0·01 *M* glutamate, 0·09 *M* sucrose, 0·000005 *M* cytochrome-*c*, 1 mgm. of nitrogen rat-liver mitochondria (isolated in 0·25 *M* sucrose). Additions: 1, 0·0014 *M* ATP + 0·03 *M* glucose + 0·8 mgm. yeast hexokinase + 0·00005 *M* atractyloside; 2, nil; 3, 0·0014 *M* ATP + 0·03 *M* glucose + 0·8 mgm. yeast hexokinase; 4, 0·0014 *M* ATP + 0·00005 *M* 2,4-dinitrophenol + 0·00005 *M* atractyloside; 5, 0·0014 *M* ATP + 0·00005 *M* 2,4-dinitrophenol. Other conditions as in Table 1

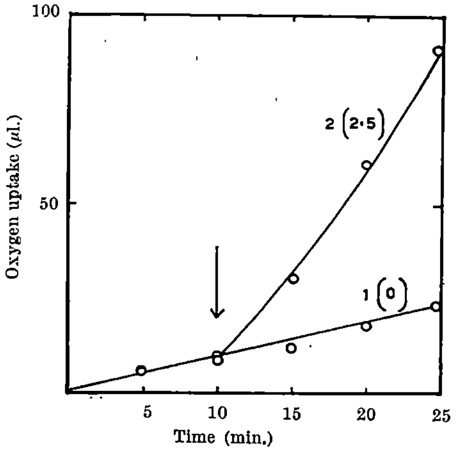

Fig. 2. Inhibition by atractyloside of the oxygen uptake stimulation induced by inorganic phosphate. The vessels contained 0·042 *M tris* buffer, *p*H 7·4, 0·005 *M* $MgSO_4$, 0·001 *M* ethylenediamine tetraacetate, 0·01 *M* glutamate, 0·09 *M* sucrose, 0·000005 *M* cytochrome-*c*, 0·8 mgm. of nitrogen rat-liver mitochondria (isolated in 0·25 *M* sucrose), 0·03 *M* glucose, 0·8 mgm. yeast hexokinase, 0·0014 *M* ATP. Additions at the arrow: 1, nil, or 25 μmoles potassium phosphate + 0·14 μmole atractyloside; 2, 25 μmoles potassium phosphate. Final volume 2·8 ml.; other conditions as in Table 1. The numbers in parentheses refer to the P/O ratios determined for the last 15 min. of the experimental period

Attempts were made to locate the action of the drug on the sequence of phosphorylation reactions. Fig. 1 shows the effect of atractyloside in a ∼P acceptors-deficient system activated by 2,4-dinitrophenol. A concentration of this substance, able to produce complete uncoupling of the respiratory chain phosphorylation, completely removes atractyloside inhibition on oxygen uptake with glutamate as substrate ; the same is obtained with β-hydroxybutyrate, succinate and malate as substrates.

Atractyloside blocks both uptake of phosphorus and the increase of respiration produced by addition of inorganic phosphate in mitochondria depleted of endogenous phosphorus by pre-incubation with adenosine triphosphate, glucose and hexokinase[5], with glutamate (Fig. 2) or β-hydroxybutyrate as substrate; consequently, it is likely that systems utilizing inorganic phosphate are particularly concerned with the inhibition of phosphorylation by atractyloside.

Because of its action on phosphorylation reactions, atractyloside appears to be a very suitable drug for work on oxidative phosphorylation; for example, according to Slater[6,7], these results could provide evidence that for the stimulatory effect of 2,4-dinitrophenol in $\sim$P acceptors-deficient systems, inorganic phosphorus is not necessary; indeed, the action of this uncoupling agent is present also with atractyloside, which inhibits phosphorus uptake. The various aspects of the antagonism between 2,4-dinitrophenol and atractyloside are under investigation. This work has been aided by a grant from the Consiglio Nazionale delle Ricerche.

Comparison between Water and Alcohol Consumption in Six Animal Species in Free-choice Experiments

Great differences exist in the inter-individual fluctuation of the voluntary intake of alcohol by laboratory rats on free choice between 10 per cent alcohol and water[1]. This is also true of laboratory mice[2]. But on the whole the average alcohol consumption within a species of animal is constant. It can be said that each species has its own specific liking for alcohol.

In free-choice experiments the results are usually expressed as the total amount of alcohol consumed. But if the data are intended to give a picture of the preference for alcohol compared with water, it would be clearer to express the results in terms of the alcohol drunk in relation to the total amount of liquid consumed. In this way the preferences of animals of different weight and species can be directly compared.

In this work the consumption of 10 per cent alcohol and water in free-choice experiments in six animal species has been studied. The animal species were: hedgehog (*Erinaceus europeus*), golden hamster (*Cristatus auratus*), guinea pig (*Cavia porcellus*), rabbit (*Lepus cuniculus*), rat (*Mus norvegicus*, albino laboratory stock), and mouse (*Mus musculus*, Swiss albino Webster).

The hedgehogs were given only fish as food, the hamsters coarse oat meal and green forage, the guinea pigs were given hay and turnips, the rabbits hay or fresh grass, the rats a laboratory food mixture and the mice a commercial food mixture. The alcohol and water consumption was noted every day except for the mice, for which it was measured every 3–4 days. The position of the bottles was changed every 2–3 days. The results of the experiments are shown in Table 1.

The hedgehogs preferred water to alcohol solution. Sometimes, however, the animals drank considerable amounts of alcohol, and it could at times be judged from their movements that they were slightly drunk. The hamsters preferred alcohol. They seldom tasted the water and, when they did so, only until they found out that they were drinking from the wrong bottle. The guinea pigs preferred water. The comparatively large consumption of fluid and the wide variations in consumption showed that the animals spilled out some of the fluid; but it could be seen that they visited the water bottle more often and only seldom the alcohol vessel. The rabbits drank about as much alcohol as water. Individual rats differ in their choice between alcohol and water. Most of them prefer water to alcohol, but some prefer alcohol. In some individuals there was a change in preference while the experiments were in progress. What is said about rats is also true of mice.

If an animal cannot taste the difference between alcohol and water or has an equal liking for both, it does not discriminate between them, and the intake of the two drinks is about the same. Rabbits belong to this group of animals. Guinea pigs, rats, mice and hedgehogs discriminate between these solutions and prefer water to alcohol. It cannot be said from these experiments whether the preference for water depends only on an aversion to the taste of alcohol or whether any negative, physical effect of the alcohol is involved. Rats at least have an absolute aversion to alcohol and not merely a relative preference for water, since if alcohol is the only solution available the amount of fluid consumed is lower than when plain water is available[3].

In contrast to the animals mentioned above, hamsters have a pronounced preference for alcohol. This has earlier been shown to be true of deer mice (*Peromyscus c. californicus*)[4] and of the mouse strain Loiseleur and Petit used[5].

In this experiment there is no absolute measure of how much an animal likes or dislikes alcohol. It is only possible to measure how much the animal likes alcohol compared with its liking for water. A third alternative would have altered the results in relation

Table 1. Alcohol and Water Consumption in Six Animal Species in Free Choice Experiment

No. of animals	Animals × days	Species	10 per cent alcohol per day (ml.)	Water per day (ml.)	Percentage drunk as 10 per cent alcohol	Alcohol–water $P <$
12	420	Hedgehog	6·8 ± 0·53	11·9 ± 1·07	36·3	0·0002
10	340	Golden hamster	5·4 ± 0·19	0·7 ± 0·01	88·0	0·0002
8	256	Guinea pig	8·7 ± 0·97	71·2 ± 2·43	10·8	0·0002
8	168	Rabbit	34·8 ± 1·32	37·3 ± 1·54	48·3	0·5
12	300	Rat	7·4 ± 0·55	17·5 ± 0·98	29·8	0·0002
10	72	Mouse	10·0 ± 5·08	26·9 ± 5·09	27·1	0·0002

to the preference for the new solution. As Lester and Greenberg[6] have shown, a third bottle containing sugar solution strongly influenced the choice of alcohol. Only if the preference for a substance is strong in every set of alternatives can it be said that the animal has a specific craving for this substance.

The reason for the preference for, or aversion to, alcohol among animals is not known. It was shown earlier that a low original alcohol consumption in a rat can be changed into a strong preference in various ways: by a deficient diet causing metabolic block[7], by damaging liver function[8] or by inducing an experimental conflict situation[9]. In our investigation all these conditions could be excluded. According to one of us[10], the choice of alcohol can be explained by the metabolic type of the animal. Perhaps differences in metabolism can explain the differences in preference for alcohol in the various animal species.

RADIOBIOLOGY

Urinary Metabolites of ^{14}C-Tetrachloroethylene in Mice

IN recent years tetrachloroethylene (perchloroethylene) has rapidly gained in importance as an industrial solvent. Its toxic effects have not been investigated very much, however, and its metabolism is almost unknown. The present work was carried out in order to facilitate the estimation of health hazards caused by exposure to this solvent.

Starting with ^{14}C-acetylene, tetrachloroethylene was synthesized essentially according to the industrial method[1,2]:

$$CH{\equiv}CH + 2Cl_2 \longrightarrow CHCl_2CHCl_2$$

$$CHCl_2CHCl_2 + OH^- \longrightarrow CHCl{=}CCl_2 + H_2O + Cl^-$$

$$CHCl{=}CCl_2 + Cl_2 \longrightarrow CHCl_2CCl_3$$

$$CHCl_2CCl_3 + OH^- \longrightarrow CCl_2{=}CCl_2 + H_2O + Cl^-$$

The crude ^{14}C-tetrachloroethylene was purified by preparative gas chromatography, and the specific activity of the purified product was 0·7 μc./mgm.

Five female mice, one at a time, were exposed for 2 hr. in a sealed flask (2·7 l.) to the solvent vapour in doses of about 1·3 mgm./gm. body-weight. 70 per cent (42–87 per cent) of the solvent was absorbed. In four days about 90 per cent of the absorbed activity was excreted, namely, 70 per cent in the expired air, 20 per cent in the urine and less than 0·5 per cent in the fæces. By chromatographic, autoradiographic and isotope-dilution methods, in part by Jondorf's method[3], the following metabolites were identified in the urine (percentage of total urinary activity): trichloroacetic acid (52 per cent), oxalic acid (11 per cent) and dichloroacetic acid (traces). No monochloroacetic acid, formic acid or trichloroethanol was found. After hydrolysis 18 per cent of the urinary metabolites were still not extractable with ether.

These results indicate the formation of an epoxide further rearranged to trichloroacetyl chloride as one metabolic pathway for tetrachloroethylene:

$$CCl_2 : CCl_2 \rightarrow Cl_2C\overset{O}{\text{——}}CCl_2 \rightarrow Cl_3C.COCl \rightarrow Cl_3C.COOH$$

This reaction has been previously shown to occur *in vitro* with the oxidation of tetrachloroethylene in the presence of non-biological catalysts[4,5].

Action of Tetracycline on the Level of Properdin

THE influence of antibiotics on the formation of antibodies has been studied by many authors. Recently, Patočka *et al.*[1] published a paper describing the inhibitory effect of tetracycline on the formation of specific antibodies of various types in infections or after immunization with brucellæ, the influenza virus and herpes in laboratory animals. Clinical experience shows that in certain infections caused by pathogenic agents (viruses) tetracycline may have a favourable effect on the course of the disease. We tried to ascertain whether in these cases this is not due to the action of tetracycline on a non-specific defence mechanism.

We therefore investigated the properdin-levels in rabbits daily for one month with intramuscular application of 25 mgm. tetracycline per kgm. body-weight. Determination of properdin was carried out by Isliker and Linder's[2] modification of Pillemer's method. Properdin was determined before the beginning of the experiment and at intervals of 10 days. Before the experiment the average properdin-level was approximately ten units, which is regarded as the normal level. During the first ten days, properdin activity increased to a varying degree in all laboratory animals, on the average to more than double its original value. On the twentieth day we noted a marked fall, in spite of the continued application of tetracycline; on the thirtieth day the level stabilized at about the normal value. Fig. 1 shows the curve of the properdin-level in a group of nine rabbits after statistical evaluation. The experiment was then repeated in a similar manner with six rabbits which were also exposed to X-rays (500 r.). The results obtained in this group were similar, except that the decrease in the properdin-level between the tenth and the twentieth day after irradiation was much more pronounced, frequently below the original level. In the control group of four rabbits the familiar decrease in properdin activity was

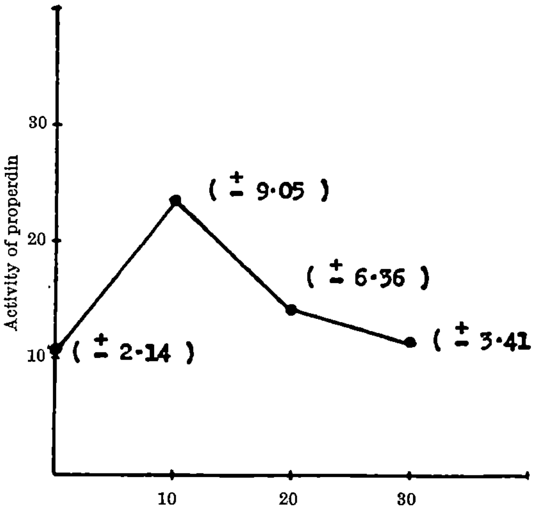

Fig. 1. Effect of tetracycline on the properdin-level in rabbits

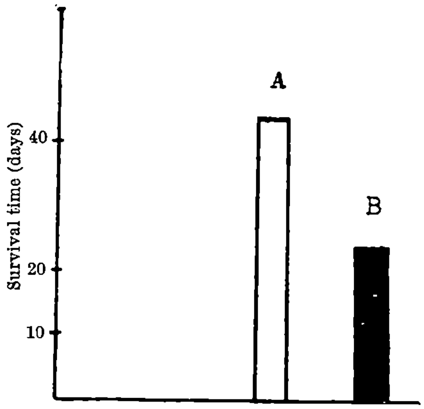

Fig. 2. Effect of tetracycline on the survival-time of irradiated rats. *A*, Group of ten rats treated with tetracycline; *B*, group of ten control rats

observed and normalization was reached on the thirtieth day.

To supplement this experiment, twenty white rats were irradiated (750 r.) and the effect of tetracycline on the survival-time was studied in ten rats against ten control animals. Fig. 2 shows a prolongation of the survival-time through the action of tetracycline. The relation between the prolonged survival-time of irradiated rats under the influence of tetracycline and the activity of the properdin system still remains a matter of conjecture; however, the results could serve as a basis for further work on the prevention of damage due to irradiation and the tetracyclines may be an effective co-factor in the suppression of the damaging effects of ionizing radiation.

HÆMATOLOGY

Thromboplastic Activity of Red Cells

WHILE a number of workers have reported thromboplastic activity exerted by hæmolysed red cells, intact red cells have been reported to display no such activity[1].

In experiments to be reported elsewhere, it has been found that under conditions more nearly approaching physiological, red cells exert a platelet-like thromboplastic activity of an order approaching that exerted by platelets.

The generation of thromboplastin was investigated first in diluted platelet-rich plasma. It was found that platelets which had thus been subjected to no manipulation exerted a much more sluggish action than that exerted by washed and re-suspended platelets. Twenty minutes might elapse after re-calcification before thromboplastic activity reached its maximum. If the plasma stood at room temperature for 2–3 hr. before re-calcification, this delay was shortened and the maximum activity developed was greater. A clot formed in the incubating plasma, if the ultimate concentration of plasma was more than 1 per cent, and it was found that thromboplastin formation was minimal until this clot formed and was separated. If the clot were allowed to stand for 2–3 min. before it was separated, thromboplastin was still minimal immediately after separation, but then developed rapidly and reached a higher maximum which approached that developed by washed platelet suspensions. Rapidly centrifuged normal plasma or slowly centrifuged plasma from thrombocytopænic patients treated in the same way developed little thromboplastic activity.

Blood was then used instead of plasma. Somewhat greater activity developed in diluted blood than in slowly centrifuged plasma, diluted to give the same plasma concentration. When blood from thrombocytopænic patients was used, diluted blood developed much greater activity than diluted slowly centrifuged plasma. There was little difference in the activities developed by normal blood and by thrombocytopænic blood.

This activity of red cells showed similar characteristics to those of platelets—in that maximum activity was displayed when the blood stood for 2–3 hr. first or when the clot was allowed to stand for 2–3 min. before it was separated; thromboplastin formation was minimal until the clot was separated. The activity was not due to hæmolysis, of which there was no evidence.

Certain discrepancies with previous observations could be resolved.

First, blood from thrombocytopænic patients displays poor prothrombin consumption. This is due to the fact that the red cells exert little thromboplastic activity until they have escaped from the clot. In the prothrombin consumption test centrifugation separates the cells from the serum before much action has been exerted. Little thromboplastic activity is then developed compared with the activity developed when the red cells are dispersed into the serum.

Other discrepancies are that the thrombin generation test of Macfarlane and Biggs[2] shows considerable difference between thrombocytopænic and normal blood, and that washed red cells have been found inactive in the thromboplastin generation test[1].

Investigation of these discrepancies revealed a difference between the behaviour of platelets and of red cells. While both develop marked activity only after coagulation has occurred, the activity exerted by red cells before coagulation has occurred is much weaker than is that of platelets. When, therefore, platelet activity of other source is minimal and when other conditions are unfavourable to coagulation, the development of red cell activity tends to be blocked. In the thrombin generation test coagulation is retarded, because the blood has not been exposed to surface activation. In the thromboplastin generation, test dilution of the constituents retards coagulation. In both cases when red cells are present, but no platelets, the red cell activity develops only slowly. By varying conditions, however, red-cell activity can easily be demonstrated in both types of test.

The difference in behaviour of platelets and red cells makes a quantitative comparison impossible, unless the conditions are specified. Moreover, since the removal of all platelets tends to block the development of red-cell activity, it might be thought that this activity would be unimportant under physiological conditions. This requires further investigation, but so far the evidence obtained tends to indicate that red cells contribute to coagulation under natural conditions and are partly responsible for the normal coagulation time found in thrombocytopænic conditions. Certain clinical differences between the hæmorrhagic states of thrombocytopænia and of coagulation defects, such as the difference in frequency of hæmarthroses, may be explicable in terms of this red-cell action.

Thalassæmia in an English and in a German Family

REPORTS of thalassæmia (major and minor) in British residents of the United Kingdom are few[1–6]. Equally few are reports of the occurrence of this abnormality in subjects of German extraction[7–14].

Recently, we have been studying the frequency of the carrier form of this abnormality (thalassæmia minor) in subjects of Greek, Egyptian, Syrian, Armenian, Italian, Ethiopian and Sudanese (Northern, 'Arab' and Southern, 'Negro') origin, using, as an absolute criterion, the presence of an increased erythrocyte osmotic resistance associated with abnormal morphological characteristics of the erythrocytes[15,16]. During our testing of healthy school children in Khartoum for this purpose we detected one English and one German girl whose erythrocytes repeatedly showed an increased osmotic resistance and, on unstained peripheral smears, anisopoikilocytosis and microcytes. Both girls (aged nine years and thirteen years respectively) were in good general health and appeared normal on clinical grounds. The abnormality was not found in fifteen other British and five other German children tested.

Similar studies carried out on the parents of the English girl (their only child) revealed that both carried the same abnormality and that both were in good general health. The mother was born in Cornwall and was of mixed Spanish–Irish–Cornish stock; she has a brother and a sister both of whom are in good health. The father was born in Malta of British parents. There is a possibility that there was some French admixture in his ancestry.

Examination of both parents of the German girl and of one brother showed that the father was carrying the abnormality and that the mother and brother were normal. The mother was born in Kothen, Anhalt, had a fair complexion and looked and felt well. She was of 'pure' German stock. The father was born in Korrig, Saarburg, and was of a dark complexion with heavy bushy eyebrows. He had suffered from malaria and had occasionally complained of easy fatigability. A recent hæmoglobin test yielded results within normal limits. His sister and his mother are said to have a similar dark complexion. His family had had close ties in Lorraine some two centuries ago.

The evidence of ties with continental Europe in the ancestry of the three parents having the thalassæmia abnormality in these two families raises the possibility that the abnormality entered both these families through their foreign antecedents. It is difficult to prove this point in the absence of any systematic work on the frequency of this abnormality in Spain and France as well as in Great Britain and Germany. Chernoff[17] lists only five references in the literature to thalassæmia in Spanish subjects, while there are only two reports of this abnormality in French subjects[18,19].

It is to be hoped that the significance of the thalassæmia abnormality in these countries will emerge in the not too distant future.

GERONTOLOGY

Expected Rate of Senescence and Age-dependent Mortality in Fish

IT is usual in fisheries investigations to assume that the mortality of wild fish from natural causes does not rise significantly with age, and calculations on this basis give reliable results for most economically important species[1–3]. Age is sometimes invoked to explain the disappearance of fish[4]: at high ages a number of species show a decline in numbers which might be due to natural ageing[5,6]; but for long-lived species the inference is that few individuals, especially in fished populations, live long enough for the effect of age to be important.

The rate of ageing has been measured actuarially in the guppy (*Lebistes*) on a large tank-bred population[7–9]. In females of this species, growth is 'indeterminate' as in larger fish, but the survival curves under conditions of medium growth are very like those of small mammals, with a limiting age of about 2,000 days. It is of interest to consider: (1) whether the time-relations of growth and senescence can be the same in a small as in a large species; (2) whether the eventual rate of senescence in long-lived fish can be inferred from the figures for *Lebistes*.

Taking the data of *Lebistes* it is possible to construct curves for other species, showing what would happen to ability to survive if hypothesis (1) hold good. Fig. 1 gives the growth-curves of 87 tank-bred female *Lebistes* by batches from an experiment still in progress, with the observed survival-curve for the whole sample to 1,100 days; the rest of the curve is supplied from previous series under similar conditions, up to 2,000 days. The median survival is about 1,140 days.

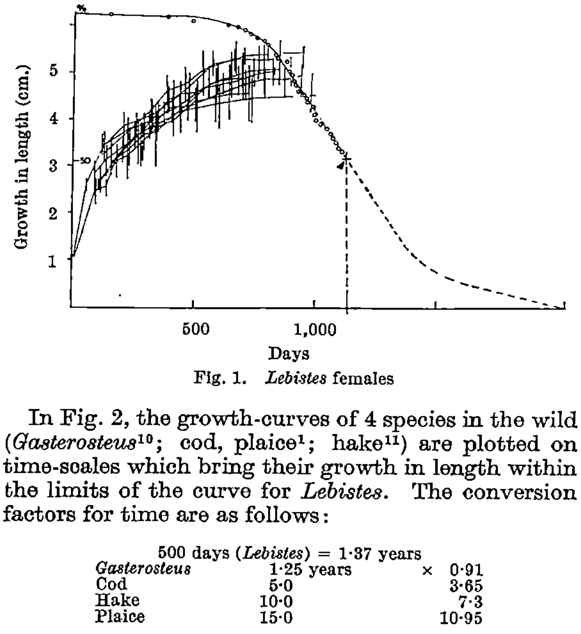

Fig. 1. *Lebistes* females

In Fig. 2, the growth-curves of 4 species in the wild (*Gasterosteus*[10]; cod, plaice[1]; hake[11]) are plotted on time-scales which bring their growth in length within the limits of the curve for *Lebistes*. The conversion factors for time are as follows:

500 days (*Lebistes*) = 1·37 years

Gasterosteus	1·25 years	× 0·91
Cod	5·0	3·65
Hake	10·0	7·3
Plaice	15·0	10·95

If these relationships hold good, populations with these growth-curves would be expected to have declined by a quarter, from senescence alone, by 2·5, 10, 20 and 30 years respectively, and the four species would have limiting ages of 5, 20, 40 and 60 years respectively. *Gasterosteus* in the wild does in fact live 2–3 years, with a few individuals surviving longer[10]. In the other species, if senescence were related to growth as in the guppy, senile mortality would not be significant within the normal expectation of life in fished populations—the modal age of plaice at catching being about 5 years[1]. The limiting ages seem likewise reasonable, except that on a basis of size one might expect the extreme life of cod to be more than 20 years. These approximations make no allowance for slower growth, however. The guppy population used in this experiment had a rather high rate of growth, and mortality at lower rates increases much more slowly. Since the relation between growth-rate and mortality increase may not be strictly linear, and since no wild population is likely to be as well fed as tank-reared fish in a laboratory, the actual survival-times in the wild may in fact be higher, but are unlikely to be less, than the approximation suggests.

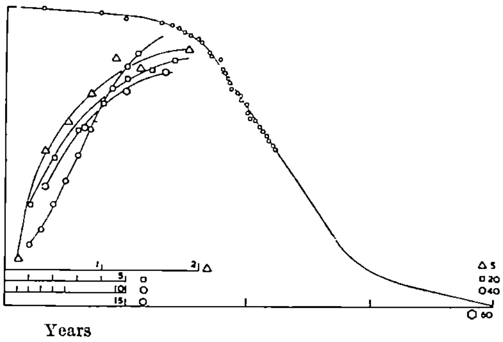

Fig. 2. Δ, Stickleback; □, cod; ○, hake; ◇ plaice

There seems accordingly to be no reason from existing data to postulate a different pattern of mortality for small as against large fish. The longest-lived freshwater fish appear to be the sturgeons, and for these the same transformation gives a limiting age of about 120 years, which agrees with the trend of recorded ages[12,13].

This work was undertaken during the tenure of a Nuffield research fellowship in gerontology.

Frequency of the 'Alpha' Rhythm, Reaction Time and Age

THE preliminary investigation described in this communication was suggested by the observations that (*a*) older people respond to a stimulus more slowly (simple reaction time is longer than in young people)[1–4], and (*b*) the dominant rhythm of the electroencephalogram, the 'alpha' rhythm, is slower in older people than in young[5–7]. These findings raised the question of whether 'alpha' frequency might be a factor responsible for differences in reaction time. The present experiment was designed to discover if simple reaction time is related to 'alpha' frequency of the electroencephalogram recorded during the time which elapses between a stimulus and a response.

Electroencephalograms were recorded from 18 subjects resting in a semi-reclined position, with eyes closed, in a darkened room. The subjects were asked to remain as alert as possible and told that, from time to time, they would hear a sound (250 cycle tone, well above threshold) to which they should respond as rapidly as possible by uttering a sound ('pow'). No forewarning was furnished to announce the presentation of this stimulus. A signal corresponding to the time the sound appeared was recorded on the chart of an Offner type *D* electroencephalogram machine along with the electroencephalogram tracings and a signal from a microphone which coincided with the subject's response. Bipolar electroencephalograms were recorded from left and right hemispheres. Each pair of surface electrodes was attached to the scalp so that one electrode was over the occipital and the other over the frontal area of the same hemisphere, with each electrode approximately 1¾ in. from the midline. An electrode on the arm served as a reference.

Thirteen of the subjects studied (18–72 years) yielded sufficiently regular and artefact-free 'alpha' rhythms to make measurement of frequency possible. The first peak or trough of a wave recorded immediately after the stimulus, and the last peak or trough recorded before the response were located, and the distance between them was measured and converted into time. Dividing this value by the number of cycles described yielded a number equal to the mean period of the 'alpha' rhythm. Only clearly defined waves were considered; cases where uncertainties arose regarding identification of peak or trough or number of cycles were excluded. In general, the mean values from left and right hemispheres did not differ. Whenever differences occurred the shortest 'alpha' period was arbitrarily used in the analysis. Reaction times were measured from the oscillograph chart and converted into time.

A total of 294 observations was obtained from the 13 subjects. The Pearson product-moment correlation (r) between reaction time and 'alpha' period was 0·38 ($P < 0{\cdot}001$). Of these observations, 78 were obtained under conditions where each subject was requested to exert maximum effort in staying alert and responding rapidly. In this case, the reaction times were shorter and showed a decrease (not statistically significant) in variability. These data are plotted in Fig. 1; in this instance $r = 0{\cdot}55$ ($P < 0{\cdot}001$).

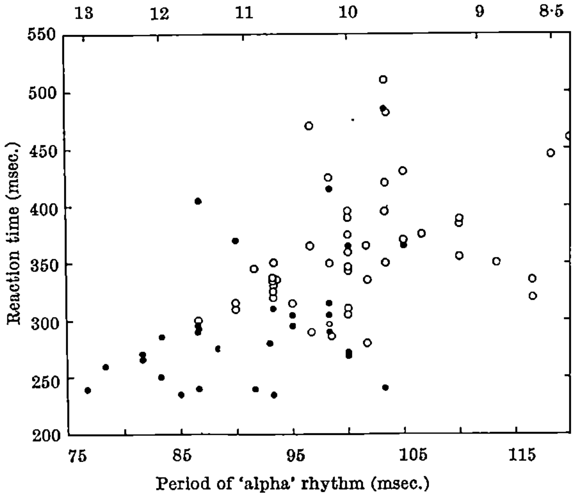

Fig. 1. Reaction time plotted against 'alpha' period. Numbers at the top of the graph refer to the corresponding 'alpha'-rhythm frequencies in c.p.s. Solid circles signify observations from subjects 18–49 years; open circles, subjects 53–72 years

Fig. 1, of course, is purely descriptive and does not distinguish between variances of individual subjects and the variance of the group. These data therefore were analysed by computing each subject's mean reaction time and mean 'alpha' period and correlating these measures. The rank-difference correlation was 0·81 ($P < 0{\cdot}01$). Finally, the subjects were split into two arbitrary groups, with 8 subjects, 18–49 years of age, in one, and 5 subjects, 53–72 years of age, in the other. Mean reaction time for the younger group was 295 msec., for the older group 367 msec. ; the difference of 72 msec. was significant ($P = 0{\cdot}05$). The mean 'alpha' period for the younger group was 90·9 msec., for the older group 102·7 msec., and the corresponding difference was also significant ($P < 0{\cdot}02$).

Thus, although data from only a small number of subjects were available, this investigation reveals the presence of a significant relationship between a person's average 'alpha' period and average reaction time: the longer the 'alpha' period (slower 'alpha' rhythm), the slower the response. It also suggests that older subjects with longer reaction times have correspondingly lower 'alpha' frequencies in the interval between stimulus and response than younger subjects with shorter reaction times. While no causal relationship is implied by the correlations, the results nevertheless lead to the speculation that the 'alpha' cycle, or some multiple of it, may serve as the unit of time in the programming of the nervous system. This possible implication is sufficient to warrant verification of our findings and further study. We need to know, for example, what specific part is played by age in this relationship, and whether the relationship holds in individual subjects.

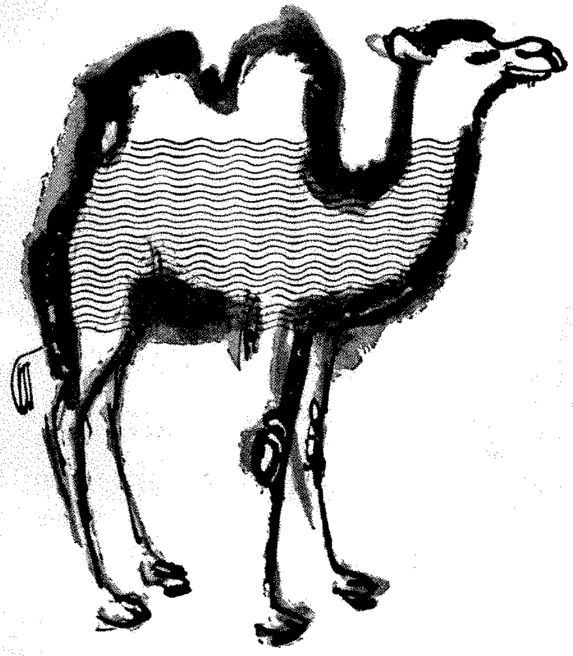
BIOLOGY

Effect of Gibberellic Acid on Growth and Indoleacetic Acid Oxidase Activity of *Lupinus albus* L. exposed to Different Photoperiods

THE leaves of 14-day-old *Lupinus albus* plants (variety *Gyulatanyai édes*) exhibit a high indoleacetic acid oxidase activity if grown under short-day conditions. In the leaves of plants exposed to long days and exhibiting more intense growth indoleacetic acid oxidase activity can be detected only after dialysis of the extracts[1]. The total phenol content of short-day exemplars is lower than that of long-day ones[2] (Table 1). Therefore, it is very probable that the indoleacetic acid oxidase activity of *Lupinus* seedlings is influenced by the phenol content of the leaves, and indirectly the growth response of plants to different photoperiods depends on the level of phenolics.

the
conservation
of water



Lack of water is enough to give anyone the hump, but when the shortage can affect the life of a community, the matter becomes serious. It is fortunate therefore that in the 1920's Rideal and others were led to consider — as an academic exercise — the effect of a non-volatile mono-molecular surface film on the rate of evaporation from a liquid substrate, and to establish that the rate could be reduced. Rideal used fatty acid films, but the Langmuirs in America showed later that cetyl alcohol films were even better.

So when the need to conserve water in semi-arid regions on a practical scale became a matter of concern — in Australia, in Africa, in the Americas, in Russia — the principle by which it could be conserved had already been established. Nevertheless it was not until 1955 that Mansfield, in Australia, was able to announce a successful process based on cetyl alcohol. The problem had been one of maintaining a durable film under adverse weather conditions, and Mansfield's solution for small reservoirs was to hold reserves of the alcohol in bead form in wire mesh rafts moored in the reservoirs. Methods for larger areas are now being actively studied.

This has led to further investigation into the spreading behaviour and durability of fatty alcohols, pure and commercial, and Unilever have collaborated in the work. For example, McArthur and Durham have studied commercial blends and shown that crystallinity is as important as composition in providing good spreading properties. Roylance and Jones have prepared pure cetyl alcohol in the stable beta form to investigate the mechanism and kinetics of film spreading, and Stewart of the C.S.I.R.O. in Australia has also used some of this material to study more particularly the effect of polymorphic change. Jones and Stephens have studied the causes of film attrition. Roylance and Jones are currently producing a range of pure alcohols for further studies.

So by contribution and collaboration Unilever is helping in the vital work of conserving water.

UNILEVER RESEARCH

Table 1. EFFECT OF TREATMENT WITH GIBBERELLIC ACID ON THE GROWTH OF 14-DAY-OLD *Lupinus albus* SEEDLINGS AND ON THE INDOLEACETIC ACID OXIDASE ACTIVITY AND PHENOL CONTENT OF THEIR LEAVES UNDER DIFFERENT PHOTOPERIODS

Photo-period	Treatment with gibberellic acid	Total heights of the overground parts (cm.)	Total phenols (expressed as 10^{-1} μgm. ferulic acid in mgm. dry matter)	Indoleacetic acid oxidase activity (μl. O_2/hr./mgm. dry matter)
Short day	–	61·6	2·57*	9·5
	+	90·4	2·40	9·3
Long day	–	107·1	3·23*	0
	+	136·8	3·28	0

* The difference between the phenol content of treated and control plants is significant only between short-day and long-day plants.

It has been shown that gibberellic acid *in vivo* reduces the activity of indoleacetic acid oxidase[3,4] probably by enhancing the synthesis of phenolic enzyme inhibitors[5,6]. Furthermore, according to Pilet, gibberellic acid exerts a direct inhibitory effect on indoleacetic acid oxidase and thereby creates a higher auxin level *in vivo*[3,7]. Therefore, a study of the effect of gibberellic acid on the indoleacetic acid oxidase activity, content of total phenolics and plant growth of 14-day-old *Lupinus albus* seedlings seemed to be warranted.

Seeds of this plant were germinated for 4 days at 25° C. in Petri dishes on filter paper moistened with gibberellic acid solution (10 mgm. in 1,000 ml.). The seedlings were then grown in pots and exposed to short-day (8 hr. daylight) or long-day conditions (8 hr. daylight + 16 hr. supplementary illumination by a 100-W. filament bulb; 2,000 lux) respectively. After the expansion of the cotyledons, the growing point of each plant was treated with gibberellic acid (2 μgm.). Controls were germinated on distilled water and the seedlings were similarly treated with distilled water. At the age of 14 days, the content of total phenolics[8] and the activity of indoleacetic acid oxidase[9] in the first leaf pairs were determined. The height of the plants was also measured. The results are summarized in Table 1.

Results similar to those shown in Table 1 were obtained with plants grown in nutrient solutions supplemented with 10 mgm. gibberellic acid/1,000 ml.

It may be seen that the growth of seedlings is promoted by gibberellic acid both under short- and long-day conditions; however, the stimulation is more pronounced with plants exposed to short days[10] and the effect is apparently additive[4].

The amount of total phenolics and the activity of indoleacetic acid oxidase is not altered by gibberellic acid treatment. The same results were obtained with gibberellic acid concentrations as high as 100 mgm./1,000 ml. The results clearly indicate that the stimulated growth of *Lupinus* seedlings evoked by gibberellic acid cannot be due to the direct or indirect (via the stimulation of phenolic inhibitors) inhibition of indoleacetic acid oxidase. It seems more likely that the effect is connected with the elevation of the endogenous auxin-level or with the neutralization of growth inhibitors[11–13]. Isotopic work of Fang *et al.*[14] also supports this idea.

The above results obtained with *Lupinus albus* might seem strange in the light of the available published data. However, we refer to observations by Hillman and Galston indicating that the indoleacetic acid oxidase of *Lupinus albus*, in contrast to that of the pea plant, cannot be influenced by red–infra-red irradiation[15].

Watanabe and Stutz[4] were also unable to show the effect of gibberellic acid on the indoleacetic acid oxidase of *Lupinus albus* leaves. However, they used 70-day-old plants and indoleacetic acid oxidase activity could not be detected in the leaves of control plants either. According to our results, this might be due to the high level of inhibitor(s)[2].

Thanks are due to Gy. Németh for the plant material and to G. L. Farkas for a sample of ferulic and gibberellic acid.

Relative Volumes of Cytoplasm and Vacuole in *Nitella*

IN order to understand the mechanism by which various organic molecules are accumulated by the vacuoles of the green alga *Nitella*, it was necessary to determine accurately the relative volumes of cytoplasm and vacuole in the cell. The unusually large size of these cells has made the genus popular as a tool for the study of biological transport mechanisms[1–5]. Single cells can be obtained up to nearly 2 mm. in diameter and more than 10 cm. in length. The contents of the large vacuole can be obtained relatively free of cytoplasm by cutting off one end and gently squeezing the solution on to a microscope slide or into a capillary para tube. There seems to be little agreement in the literature concerning the relative volumes of cytoplasm and vacuole. Thus Brooks[1] arrived at a value based on intracellular distribution of radioactive potassium and estimated 33 per cent cytoplasm, 67 per cent vacuole. Holm-Jensen *et al.*[2] measured the depth of the immobile chloroplast layer plus the streaming cytoplasm by differential focusing with a water-immersion objective, and the diameter of the cell with a micrometer eyepiece in a dissecting microscope. Calculations from their results give values of 10 per cent cytoplasm, 90 per cent vacuole. Recently, MacRobbie and Dainty[4], measuring the rate of loss of sodium-22 from *Nitellopsis* cells previously loaded with the isotope, calculated that the cytoplasmic compartment consisted of about 3 per cent of the cell. In a similar fashion, using potassium-42, Diamond and Solomon[5] arrived at values of 1·8 per cent cytoplasm.

For our experiments we used *Nitella opaca* Ag, gathered from a stream in southern Sweden and maintained in tap water. We used several direct methods to measure the volumes of the two compartments. In preliminary experiments we cut the end of a cell and squeezed out the total contents directly into a capillary tube. The tube was sealed and centrifuged. Volumes of the fractions were measured by projecting the image of the tube and contents into tracing paper, cutting out the paper, and weighing the areas. The total cytoplasm constituted 8·7 per cent of the recovered volume. Three distinct fractions were observed. The average volumes for the eight cells measured were: dense green chloroplast fraction, 3·8 per cent; translucent cytoplasm (probably the streaming layer), 4·9 per cent; clear supernatant vacuole, 91·3 per cent. There were two important sources of error in this technique which tend to give low values for the cytoplasm. It was impossible to get all the chloroplast fraction out of the cell, and some of the green material adhered to the walls of the capillary tubes.

In order to overcome these difficulties we placed intact cells in glass tubes, sealed one end, filled with water, and centrifuged at high speed with the tubes in a horizontal position. The three cellular fractions separated very distinctly. By projecting the image of the centrifuged cell into tracing paper, as above, we measured the following average values (per cent) for eight cells: chloroplast fraction, 4·1; streaming cytoplasm, 5·8; total cytoplasm, 9·9 (range, 8·8–11·8).

Since the technique of centrifugation probably compresses the *in situ* volume of the chloroplast and streaming cytoplasm fraction, we measured the dimensions of the sum of both the chloroplast and cytoplasmic layer with a calibrated focusing micrometer on a microscope with a water-immersion lens. Then, by measuring the diameter of the cell with a micrometer eyepiece, it is possible, assuming the solid geometry of right cylinders, to calculate the volume occupied by the two fractions. For eight cells the values are: range of diameter, 375–550μ; range of depth of cytoplasm, 11·2–16·1μ; average volume of cytoplasm, 12·2 per cent (range, 9·3–14·1 per cent).

In the fourth technique, we used the fixation of cells by various methods among which the Navaschin–Karpechenko technique appeared to cause the lowest degree of distortion, though invariably leading to some plasmolysis. Measurements were obtained from photomicrographs of microtome sections and suitable calculations made. The dimensions of a typical cell were found to be: thickness of cell wall, 7·9μ (sections of fresh material gave somewhat higher values); thickness of total plasmatic layer, 17·8μ; overall diameter of whole cell, 460μ. The relative volume of cytoplasm is therefore 14·4 per cent.

The last three methods used give values for cytoplasmic volume of 9·9–14·4 per cent, and are in rather close agreement. Both in living material and in the microtome sections the innermost part of the cytoplasm was seen to have a somewhat foamy appearance, which explains, at least in part, the difference between the values obtained by centrifuging and those obtained by direct measurements. We can say, with some degree of certainty, that the cytoplasm occupies at least 10 per cent of the physical volume of the cell, as had been suggested by Holm-Jensen *et al.*[2]. The value is at great variance with that of MacRobbie and Dainty[4] and Diamond and Solomon[5]. There is no doubt that there is some 'compartment' comprising 2–3 per cent of the cell which loses alkali metal ions in the fashion described by these workers. This compartment is not, however, the total cytoplasm. Rather, it might be the matrix of the immobile chloroplast fraction. As judged by qualitative microscopic observation, we estimate that the matrix occupies approximately 2–3 per cent of the volume of the cell.

Our work suggests that some compartments of the cell are not limited by the finite membranes of the tonoplast and plasmalemma, but should be considered as volumes of the cell which differ in physical and chemical properties which influence their permeability behaviour.

Inoculation of Pine Stumps against Infection by *Fomes annosus*

RECENT trials have shown that inoculation of pine stumps with oidia of *Peniophora gigantea* prevents infection by spores of the fungus *Fomes annosus*, causing root-disease of conifers. *P. gigantea* is an active wood-rotting fungus which under natural conditions often competes with *F. annosus*, but for various reasons does not provide consistent control. It is a far more effective competitor than wood-inhabiting microfungi such as *Trichoderma viride* and *Penicillium* spp., which seldom colonize a fresh stump surface at all freely.

To prepare cultures of *P. gigantea*, pine wood-blocks of 3 cm. × 3 cm. × 1 cm. are autoclaved in batches of one hundred, inoculated with a suspension of oidia and incubated at 22° C. for 10 days. They are then sealed individually in small, sterile polythene bags, in which condition they remain usable for many months. The suspension of oidia is prepared by shaking a wood-block culture with about 100 ml. tap water for 1 min. It is then diluted 5–10 times and sprayed on to the stump surface by means of a large syringe directly after felling. According to the size of stump, 3–5 strokes suffice: these deliver 2–3 ml. suspension containing some 1×10^6 viable oidia. It is desirable to use a fresh suspension each day. In cold weather oidia may be suspended in 10 per cent ammonium sulphate, which considerably depresses the freezing point without greatly affecting spore viability.

In ten experiments, involving some 400 stumps of *Pinus sylvestris* or *P. nigra* var. *calabrica*, samples taken after 6–12 months showed that inoculation had consistently prevented infection by *F. annosus*, whether derived from natural sources or from adding up to 3,000 spores per stump. About 90 per cent of inoculated stumps produced sporophores of *P. gigantea* within a year, thus increasing local spore production of this useful competitor. The treatment was also effective in preventing growth of *F. annosus* into stumps, the roots of which were inoculated with the parasite soon after felling: in five stumps excavated a year later, no roots were found to contain *F. annosus*. By contrast, in root-inoculated stumps treated with creosote or urea at the time of felling, two-thirds and one-third of the roots, respectively, were occupied by the parasite. With naturally infected pine stumps, however, *P. gigantea* was rather less effective because it seldom replaced *F. annosus* in resinous roots already dead at the time of felling.

This method should prove useful in preventing entry of *F. annosus* into first-rotation pine stands of special value, such as experimental plots; it might also find wider application in young forests where *P. gigantea* is as yet uncommon. Despite the limitation mentioned, inoculation of stumps with *P. gigantea* may well be preferable to treatment with chemicals[1] in stands where *F. annosus* has already become established. Preliminary trials suggest that it may be possible, by selecting appropriate saprophytes, to protect stumps of other conifers against infection by *F. annosus*.

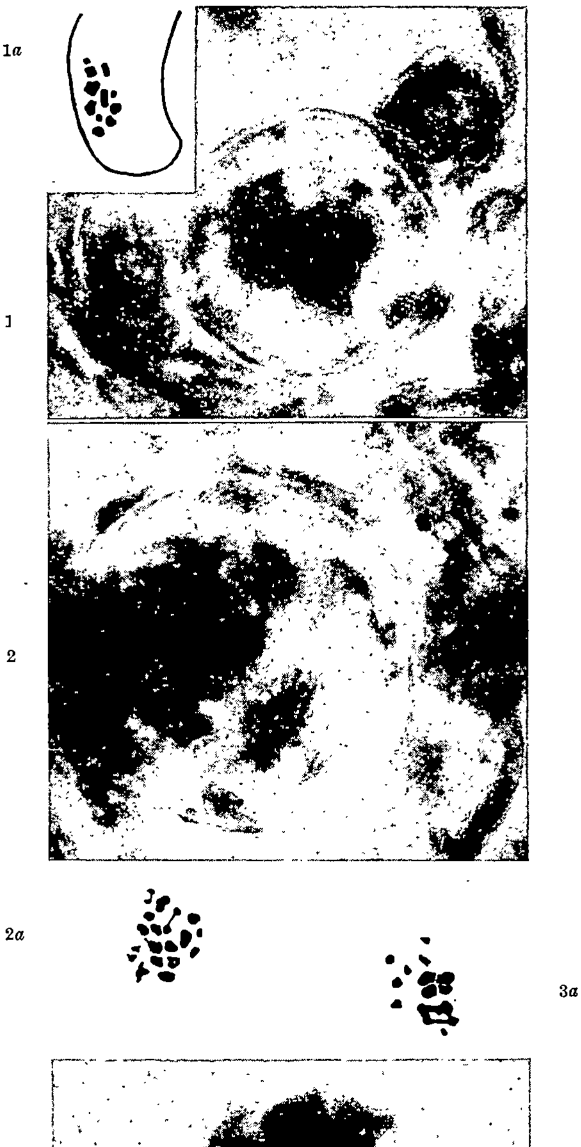
Meiosis in the Oogonium and Antheridium of *Pythium debaryanum* Hesse

Aceto-orcein squash preparations of a culture of *Pythium debaryanum* Hesse were found to have nuclei in division in the oogonia and the antheridia (Figs. 1 and 2). The stage of division was usually rather more advanced in the oogonium than in the antheridium. The oogonia had 2–6 nuclei undergoing division, the antheridia usually one, occasionally two.

The haploid number of chromosomes is approximately twenty (Figs. 2, 2*a*), but an exact count has not been possible so far, partly because of the smallness of the chromosomes and partly because of certain irregularities. At first it was assumed that these divisions were mitotic, but a closer examination disclosed side views of configurations at early anaphase with loops such as would be expected to result from interstitial chiasmata. Also, certain irregularities such as early separation of failure of pairing indicated that these divisions were meiotic. No metaphases were seen in the hyphæ or sporangia, even after camphor treatment, and it is concluded that vegetative nuclei do not normally pass through an ordinary metaphase stage when dividing. The occurrence of metaphases in the oogonia and antheridia therefore indicates that these may be special divisions, that is, meiotic divisions.

Full confirmation of this was obtained when configurations of more than two chromosomes were obtained (Figs. 3, 3*a*). Such configurations could only occur in meiosis. This indicates that *Pythium debaryanum* is a structural hybrid, or a polyploid which may well account for the failure of previous attempts to germinate the oospores.



Figs. 1–3. 1. Oogonium and antheridium, metaphase I in antheridium; (1*a*) drawing of metaphase. 2. Oogonium and antheridium. Oogonium with 4 metaphases, 1 in focus. (2*a*) Drawing of metaphase plate. 3. Side view of metaphase I in oogonium showing a multiple configuration. (3*a*) Drawing of metaphase. (Figs. 1 and 2 × *c*. 2,600 ; Fig. 3 × *c*. 4,300)

The Peronosporales have generally been considered to be haploid with meiosis occurring in the first division of the oospore nucleus. However, there is little or no direct evidence for this view. It is very unlikely that *Pythium debaryanum* should have a different life-history from the rest of the group, and I feel sure that further work will show that the Peronosporales and probably the Biflagellatae as a whole are diploids in the vegetative stage with meiosis occurring in the oogonium and antheridium. It is very suggestive that two successive divisions have been reported to occur in the oogonium and antheridium of *Albugo* sp.[1]. The genetical work on the Biflagellatae is very scant, but according to Raper[2] the complex pattern of sexuality in *Dictyuchus* reported by Couch[3] could be accounted for by polyploidy or duplicate factors. This suggestion of Raper is in accordance with the present observations, in indicating that members of this group may be diploid rather than haploid as has been previously supposed.

I am indebted to my husband and Dr. B. J. Harris for helpful discussions and to the latter for the photomicrographs.

Note added in proof. Meiosis has been observed recently in the oogonium and antheridium in *Phytophthora cactorum,* which has approximately nine bivalents.

Effect of Varying Doses of Undiluted Semen on Fertility in the Domestic Fowl

SEVERAL reports[1-3] have appeared on the relationship between dose of undiluted semen and fertility in chickens, yet there is little evidence on the minimum volume of undiluted semen necessary (*a*) to produce any fertility, and (*b*) to establish the maximum or optimal level of fertility. The relationship between spermatozoa number and fertility has been investigated by using varying doses of semen diluted with synthetic diluents and seminal plasma[4,5]. However, recent work[6,7] indicates that synthetic diluents and even seminal plasma can alter the metabolic rate and perhaps even the life-span *in vivo* of fowl spermatozoa. This is a brief report of an experiment undertaken to establish the minimum volume of undiluted fowl semen required to produce any fertile eggs, and minimum volume necessary for optimal fertility.

Semen was obtained from 15 males selected randomly from each of two random-bred strains—the Ottawa S.C. White Leghorn control strain[9] (Leghorn control) and the Ottawa meat control strain[10] (meat control). All inseminations were made into random samples of females from two selected strains of S.C. White Leghorns[9] that were known to be similar in production traits. Both strains of females were highly fertile.

Semen was collected from each male and pooled by strain after rejecting samples which were contaminated and contained 'clear watery fluid'[7]. Fifteen doses of semen were used (Fig. 1) varying from 0·0002 ml. to 0·15 ml. The experiment was repeated for six days. Each day two hens were inseminated with each dose from each of the two strains of males. Twenty-four hens were inseminated with each dose for a total of 360 inseminations. Only hens that had laid already on that day were inseminated.

Glass pipettes fitted to a 1 ml. tuberculin syringe by rubber tubing were used to measure and deliver the semen. Four different-sized pipettes were used, the smallest graduated to 0·0002 ml. with a diameter of 0·25 mm. It was recognized that the error in measurement and delivery of the smallest dose was quite high, but not greater than ± 0·00005 ml.

Following the single insemination, all hens were trap-nested and the eggs were marked, dated and stored in a holding room at a temperature of 50° F. and with a relative humidity of 85–90 per cent. They were incubated weekly, until all hens were completely infertile.

Differences between the two strains in semen density were not significant. This confirmed our previous findings[10]. Therefore, the data on spermatozoa number from the two strains were pooled. Fertility was measured as the duration of fertility in days, following a single insemination[2]. The results are plotted in Fig. 1, showing both the size of the dose and the number of spermatozoa per dose.

The differences between the strains were highly significant. Differences between strains and between breeds in duration of fertility are a relatively widely spread phenomenon[2,11,12].

The duration of fertility for the Leghorn control and for the meat control increased with an increase in the semen dosage up to 0·01 ml. and 0·006 ml. respectively. Although there was a slight increase in fertility with doses above these levels, it was not significant. With doses as small as 0·0002 ml. some fertility resulted in both strains.

The relationship between fertility and spermatozoa number should be considered in the light of recent developments in the technique of semen collection[8,13]. Fowl semen collected free of contaminating fluids contains, on the average, six to seven million spermatozoa per ml. of semen[8,10]. This is double the concentration reported by most other workers who, no doubt, were using semen contaminated to some degree[4,5]. In this present experiment the minimum number of spermatozoa required for optimal fertility was 40 and 66 million for meat control and Leghorn control, respectively. These estimates are much lower than those reported by others[4,5]. There is little doubt that the use of careful semen collection and insemina-

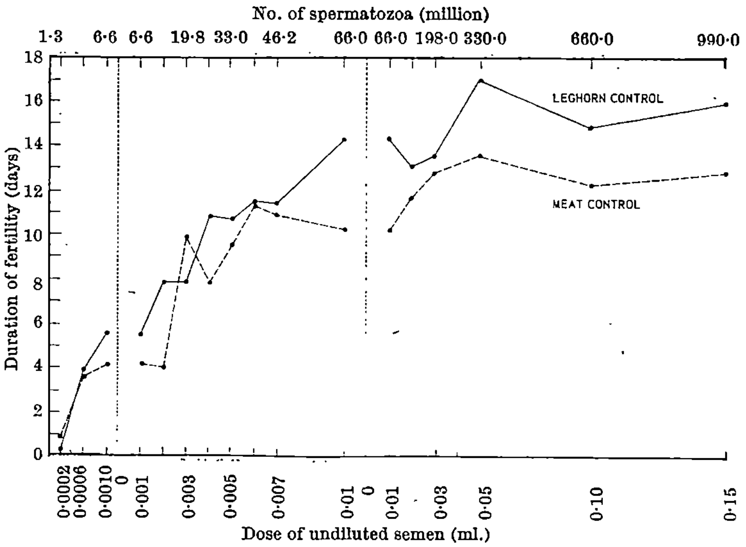

Fig. 1. Relationship between the dose of undiluted semen (number of spermatozoa) and the duration of fertility in two strains of domestic fowl

tion techniques have contributed to the results obtained.

Copepod *Ommatokoita elongata* (Grant) in the Eyes of the Greenland Shark—a Possible Cause of Mutual Dependence

In July 1959[1], and in July–August 1960, I had the opportunity to take part in Greenland shark fishery with Norwegian commercial sealing vessels in east Greenland waters. Data on this shark were collected, supplemented with information received from experienced Greenland shark fishermen.

The sluggishness of this shark is proverbial, and it is to many a puzzle how such a sluggish fish is able to capture live prey.

The information received from the fishermen tends to show that, besides many other marine animals, the char, *Salmo alpinus*, has been repeatedly found in stomach contents of this shark, even so freshly swallowed that it could be used for human consumption on board. According to information received from several skippers, some of the chars found in shark stomachs had been cut by the shark's teeth when captured, and in such cases their tail parts were invariably missing in the stomach contents. This naturally leads to the assumption that the char has been swallowed head foremost by the shark. It is believed very strongly by Norwegian fishermen, who have been fishing for Greenland sharks, that its potential prey is lured to swim toward it by the 'white things', that is, the copepod *Ommatokoita elongata*, attached to its eyes. The copepods are said to be luminous by some fishermen.

The infestation with this copepod in south-east Greenland waters was found to be as follows :

Of the 1,505 sharks inspected, 1,270 (84·4 per cent) were infested in both eyes, 218 (14·5 per cent) were infested in one eye only, and only 17 sharks (1·1 per cent) were not infested. It is, however, possible that copepods have been lost during the haul or have been too small to be observed easily.

One copepod in each eye is the rule, but in some cases, included in the numbers given above, two, or rarely more, specimens were attached to one eye. Very rarely specimens were found attached to the skin near the eyes. The copepods are firmly attached to the cornea by a small disk. Numbers of small circular marks on the cornea are thought to be scars left by previous infections. The copepods were found to vary in length from 3–4 mm. to about 70 mm., including the egg sacks. The smallest copepods had evidently become attached recently, and there is thus reason to believe that uninfested sharks were only temporarily free of this copepod. The copepods are whitish-yellow in colour, and in particular adult specimens with large egg sacks are very conspicuous. The cornea was often found to be opaque, and in cases of heavy opacity, copepods were not found to be present.

Table 1

		O. elongata				
1959	Total	Both eyes	Right eye	Left eye	Absent	Not examined
Umivik Fjord	264	205	21	21	2	15
Umivik Bank	10	3	2		1	4
1960						
Umivik Fjord	664	519	49	50	9	37
Umivik Bank	244	173	11	12	2	46
Bank area east of Kangerdlugsuak Deep	2	2				
Off Deception Island	473	368	23	29	3	50
	1,657	1,270	106	112	17	152

According to the data collected, this copepod appears to be equally common in both small and large sharks. Differences in infestation relative to sex were very small. As is apparent from the list above, only small variations in infestation are observed between the different fishing localities.

It may be added that mainly small and medium sharks of both sexes were caught in the fjords and near land, while only large fish, from about 3·5 m. to nearly 5 m. in length, were caught on the banks. These were, with one exception, females only.

I have not been able to confirm the fishermen's belief that the copepods are luminous. No bioluminescence could be observed by the human eye in specimens kept in sea water in total darkness.

O. elongata is grouped in the family Lernaeopodidae which, according to Harvey[2], is not included in any of the two copepod sub-orders, Calanoidea and Cyclopoidea, to which bioluminescence seems to be restricted. It is therefore unlikely that *O. elongata* is able to produce light. However, histological examination has not been undertaken.

It may be argued that when the amount of light present in the sea is above a certain minimum, the whitish copepods will show up against a dark background. However, the effect of the tapetum lucidum of the shark's eyes in weak light conditions is not known.

It is generally accepted that many fishes, such as the angler fish (*Lophius piscatorius*) and ceratioid deep-sea fishes, use the first dorsal fin ray as a lure or 'fishing rod' for attracting prey[2]. Although the fishermen's assumption that the copepods in the eyes of the Greenland shark serve a similar purpose sounds rather far-fetched, it should not be entirely excluded. But if such should really be the case, of which I am so far not convinced, then the copepod is of some benefit to its host, and a mutual dependence, which may be classed as a case of mutualism, may be anticipated to exist between the two.

I am fully aware that this view is highly speculative, but it is felt to be of sufficient interest to attract biological attention, in order that other workers who have the opportunity to add further knowledge may do so.

Occurrence of *Eutrichocheles modestus* (Herbst) in the Near-shore Waters of Porto Novo, South India

Faunal studies of this region on the Coromandel Coast have been in progress for some years. Some interesting finds have been reported[1-3] recently, after the establishment of a marine biological laboratory at Porto Novo (11° 29′ N. and 79° 47′ E.), and this communication relates to the occurrence of the extremely rare decapod crustacean *Eutrichocheles modestus* (Herbst) (Fig. 1). A specimen 80 mm. in length (from the tip of the rostrum to the posterior extremity of the telson) was first obtained from a seine net operated by local fishermen at about the 10-fathom line (about 4–5 miles from shore) in February 1960. This area is well within the limits of the continental shelf, which extends to about 20 miles along this coast. Another specimen measuring 75·2 mm. in length was obtained in January 1961.

From a survey of the literature it would appear that only two specimens of this decapod have so far been obtained, and the exact source of neither of these is known with certainty. The first specimen described by Herbst (1794)[4] as *Cancer modestus* was probably taken in the East Indies, and the other specimen on which Wood-Mason (1875)[5] based the present generic name was caught somewhere off the Arakan coast of Burma. The latter specimen seems to be the only example in existence now[6]. With the present discovery of *Eutrichocheles modestus*, de Man's statement[7] "that this extremely rare form will probably prove to occur also in the Indian Archipelago" would appear prophetic.

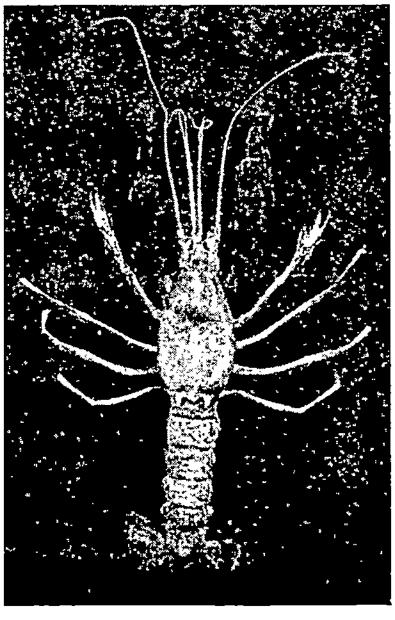

Fig. 1 *Eutrichocheles modestus* (Herbst)

The main features of the specimens from Porto Novo conform very closely to the earlier descriptions, but the following supplementary observations may be made. The fresh specimens appeared rather pink in colour and with preservation they have tended to become white. One is therefore reminded of the red pigment mentioned by Herbst[4] and the white colour referred to by Chopra[6]. Further, the cornea appears to be pigmented unlike what Chopra observed. Again, in our specimens the rostrum ends in a rather sharply pointed tip, and with regard to the abdominal segments, the teeth at the anterior margin of the fifth are rather indistinct compared with those on the third and fourth segments. There is a median groove in the telson running from the notch at its posterior margin, to the middle, where runs a transverse row of spines. The exopod of the uropod also has hairs. This feature was described by Chopra[6].

Unlike the Indian Museum specimen, the right cheliped and not the left is the bigger in our material and both the chelipeds are profusely covered with hair-like outgrowths. The nature and distribution of the tubercles and spines in the different regions of the chelipeds would also appear to vary from what has been described by the earlier authors.

When more specimens of this curious creature become available a detailed investigation of its anatomy will be undertaken, when it may also be possible to discuss its systematics in a more precise manner than has hitherto been possible.

We thank Mr. L. K. Sourirajulu, of the Zoology Department, for directing our attention to this animal in the net along with a collection of numerous other organisms. We also thank Mr. G. Ramakrishna, of the Zoological Survey of India, for help with a survey of literature. Our thanks are due to Prof. R. V. Seshaiya for his interest.

LIMNOLOGY

A Lake in British Columbia containing Old Sea-Water

Stimulated by Strøm's reports[1,2], and by N. M. Carter's speculations (oral communication), we have made a preliminary examination of Powell Lake, British Columbia, and find conditions therein similar to those described by Strøm for Lakes Tokke and Botnvatn in Norway.

Powell Lake is a fjord lake about 50 km. long and 2 km. wide. The outline of the lake and the form of the mountains rising above it resemble the many fjord-like inlets along the British Columbian coast. However, the southern end of the lake (49° 53′ N., 124° 32′ W.) is separated from the adjacent

Strait of Georgia by a rocky sill 46 m. above sea-level.

A dam built fifty years ago downstream from the sill raises the lake-level to 56 m. above sea-level. Some 16 spot soundings made prior to our investigations indicated a maximum depth of 418 m., but the maximum which we recorded was 358 m. Of 10 soundings made by us in the southern part of the lake, a basin 10 km. long, 7 fell in the range 346–358 m. suggesting a nearly horizontal floor in this part. This lower part of the lake is separated from the upper part by two narrow straits which, judging from the few early soundings, are appreciably shallower than the basins above and below. The upper basins receive nearly all the important streams tributary to the lake. Turbidity currents which might develop directly from the muddy streams or by mud-slides from actively growing deltas are likely to be trapped in the upper basins, leaving the lower basin free, or nearly so, of invasions at depth by turbid water.

The salient water characteristics which make the Lake worthy of remark are shown in Fig. 1. Results were obtained on May 29 and 30, 1961, from the centre of the lower basin where the depths exceeded 350 m. The considerable rise in temperature of nearly 5° C. from 100 m. to the bottom was the first indication that the deeper water needed a significant salt content for stability. The chlorinity of the samples was determined by titration with silver nitrate and the salinity computed from Knudsen's relationship. It should be noted that this relationship is not entirely valid due to appreciable variations in the ratios of the ionic constituents of the water of the Lake from those found in modern sea-water. For example, the correction of the chlorinity titration for the presence of hydrogen sulphide (Table 1) reduces the salinity from 16·92 to 16·58 in the 334-m. sample. However, density and electrical conductivity values for the deep-water samples agreed closely with those for sea water of the same salinity. The presence of large amounts of dissolved gases in the bottom 50 m. of the water column was evident from the voluminous degassing which occurred while drawing the samples. These oxygen-depleted bottom waters had an *in situ* *p*H of 6·7–6·9 and showed a distinct yellow colour which increased in intensity with depth and was evidently due to dissolved organic matter. As shown in Table 1, the high hydrogen sulphide content of the bottom water results in the expected concurrent low iron (II) concentration. Curiously enough, this is a condition opposite to that found by Strøm[1] for Lake Tokke which in comparable chemical properties was otherwise similar to Powell Lake.

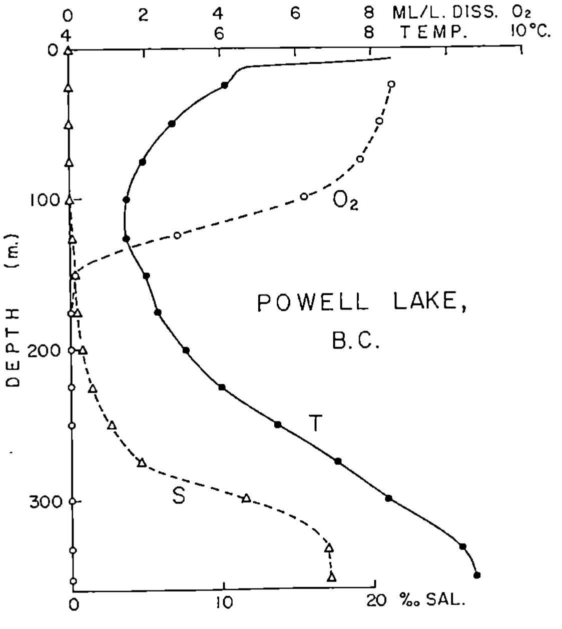

Fig. 1. Distribution of temperature, salinity and dissolved oxygen in Powell Lake, British Columbia

Table 1. Some Chemical Constituents of Powell Lake Bottom Water (334 m.)

Constituent	Concentration (mgm./l.)
Chloride	9,400
Sulphate	0
Bicarbonate	2,050
Total sulphide (H_2S, HS^-)	> 89
Total iron (dissolved and particulate)	< 0·5
Inorganic dissolved phosphate (P)	0·015
Inorganic dissolved silicate (Si)	10·4
Dissolved carbon dioxide	about 200
Dissolved methane	present*

* Identified by gas phase chromatography.

In the neighbouring inlets in which the stability of the water is high in the upper layers but decreases to the bottom a minimum temperature of 6°–8° C. is common at about 50 m. depth, while the deeper water is isothermal within 1° C. The minimum of lower value and greater depth in Powell Lake is attributed to the lower stability in the upper 150 m., which permits winter cooling to a greater depth. The considerable temperature gradient in the deeper water is associated with high stability of the deeper water due to the salinity gradient. It is possible that the temperature gradient is maintained by flow of heat through the bottom of the Lake. A flow of 40 cal./cm.^{2}/yr. would require the eddy heat conductivity in the water to be 3–4 times the molecular conductivity.

The saline water is presumed to have entered the Powell Lake Valley first during the disappearance of the last Cordilleran ice sheet close to 13,000 years ago. At this period the land was submerged in the vicinity of the Strait of Georgia at least locally to the present 175 m. contour[3]. Quaternary marine fossils reported from one point on the east side of Powell Lake may belong to this stage. With continued uplift, during and following the disappearance of the ice sheet, the rocky sill at the lower end of the Powell Lake basin shoaled, became emergent, and gradually rose to its present position above the sea. Radiocarbon dates from the opposite side of the Strait of Georgia, 70 km. to the south[4], indicate that the sea stood at the present 52-m. contour about 12,250 years ago and there is no suggestion that this level was afterwards submerged. In the lower Fraser Valley, 180 km. south-east of Powell Lake, the sea withdrew from the 60-m. contour before the last ice disappeared, some time between 11,000 and 7,300 years ago. In the Fraser Canyon, 220 km. east of Powell Lake, the ice sheet had disappeared and the Fraser River flowed below the present 75-m. contour 9,150 years ago. At the stage when Powell Lake was cut off from the Strait of Georgia it is possible that the waters of the Strait had a salinity less than that of the present 30–31$^{0}/_{00}$ due to dilution by large quantities of melt water from the dwindling ice tongues still present in parts of the lower Fraser valley[5,6] and at the head of at least one inlet[7] leading into the Strait.

We wish to acknowledge the assistance of Mr. J. Dice of Powell River, B.C., who made available and

operated his yacht, *Samarie*, from which our observations were made.

HISTOLOGY

Use of Veronal Buffers in Formalin Fixatives

FORMALIN 'buffered' with veronal (diethylbarbituric acid) has been used as a tissue fixative by Zacks and Blumberg[1] and by Dales[2], and as a storage fluid for fixed and stained specimens by Essner *et al.*[3]. It does not appear to have been realized, however, that veronal reacts rapidly with formaldehyde to produce a substance that has no buffering capacity within the physiological range of *p*H values.

This was observed when the osmium tetroxide in Palade's veronal–acetate buffered fixative[4] was replaced by sufficient formaldehyde to give a final concentration of 4 per cent. The composition of the mixture was 2·6 ml. of analytical reagent quality 36 per cent formaldehyde, 5 ml. each of *M*/7 sodium veronal and *M*/7 sodium acetate, and 5·5 ml. of *N*/10 hydrochloric acid in a total volume of 23 ml. By analogy with the corresponding osmium tetroxide fixative, the formalin variant was expected to have a *p*H of about 7·2. In fact, the measured *p*H was 9·8, indicating that the formaldehyde had reacted with the sodium salt of the monobasic veronal[5] to produce a neutral product, with concomitant liberation of alkali.

The experiment was repeated several times under carefully controlled conditions, and the resulting solutions were titrated with *N*/10 hydrochloric acid, using a Radiometer (Copenhagen) automatic titrator Type *TTT*1 and recording titrigraph type *SBR*2. The results indicated that one molecule of alkali was produced for every molecule of sodium veronal undergoing reaction, and that all the veronal was converted into the reaction product in the presence of the excess formaldehyde in the mixture. The shape of the titration curve was almost indistinguishable from that of a solution containing the same concentrations of sodium acetate and formaldehyde as those in the fixative, but from which the veronal salt had been omitted. It is clear, therefore, that the reaction product of veronal and formaldehyde has no buffering capacity. Any residual buffering action in formalin variants of Palade's fixative is due solely to acetate and, consequently, effective only in the range of approximately 3·6–5·8.

The *p*H of veronal-treated formalin fixatives may, of course, be adjusted to any convenient value near neutrality. The solutions will still act as fixatives, for in the case described here, there is a concentration of free formaldehyde of about 3 per cent, which is adequate for many fixation purposes.

It is not clear why the effect described here has not been observed before. It is possible that the magnitude of the change in *p*H, and that of the adjustment necessary to restore the *p*H to the required level, has been overlooked through the use of inadequate detection methods. The effect is immediately obvious, however, when a sensitive *p*H-meter is used, and such instruments are essential for the preparation of buffered solutions for cytological and cytochemical purposes.

While the reaction of unsubstituted barbituric acid with formaldehyde is known to produce C,C′-methylene*bis*barbituric acid[6], the reaction with disubstituted barbituric acids does not appear to have been described before. Since the possibility of methylene bridge formation between carbon atoms is excluded by the presence of the two ethyl groups in veronal, the observed effect is probably due either to the formation of a neutral N-hydroxymethyl-derivative, or of the corresponding N,N′-methylene*bis*-compound. Structural investigations have not been made to confirm which of these suggestions is correct.

We have commented elsewhere[7] on the value, for electron microscopy, of formalin-based fixatives to which veronal and other buffers have been added.

CYTOLOGY

Sub-Chromatid Structure and Chromosome Duplication in *Vicia faba*

A QUADRIPARTITE structure of chromosomes has been inferred from certain anaphase configurations in mitosis and meiosis, such as the two-side-arm bridges found in irradiated meiosis in *Uvularia*[1] and *Lilium*[2]. Similar bridges have been seen in endosperm mitosis[3,4]. Wilson *et al.*[5] have clearly demonstrated the sub-chromatid nature of such bridges in *Trillium*.

The present work has aimed at determining whether sub-chromatids are demonstrable in *Vicia faba*, the species used by Taylor *et al.*[6] for autoradiographic analysis of chromosome duplication.

Meiotic material was fixed at half-hourly intervals 2–5 hr. after irradiation at a dosage of 36 r. Root tips (laterals), grown in distilled water, were fixed 1–1·5 hr. after 108 r. irradiation. Dosage-rate was 36 r./min. at 6 m.amp., 200 kV., with a 0·85 mm. copper/0·5 mm. aluminium filter. Focal distance was 40 cm., half-value layer 1·55 mm. copper. Timing trials indicated that anthers in mid- and late-first anaphase at fixation would have been in stages of late diplotene to metaphase 2–2·5 hr. previously. Divisions in control material were regular except for a very low frequency of breakage and reunion.

Pollen mother cells in first and second anaphase showed a high frequency of two-side-arm bridges similar to those described for *Trillium*[5] (Fig. 1*a*).

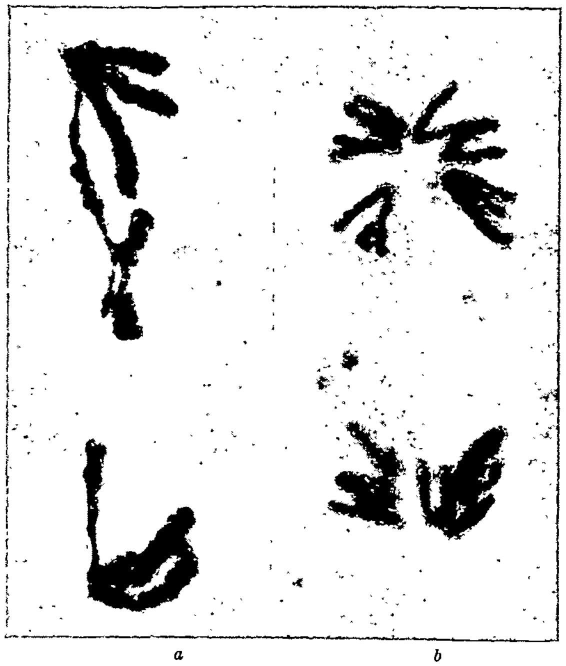

Fig. 1. (*a*) Metacentric chromosome of *V. faba* at anaphase I showing true two-side-arm bridge. (× 1,900). (*b*) Anaphase I showing *Y*-shaped chromatid with corresponding deficient chromatid at opposite pole. (× 1,000)

It was possible to trace sub-chromatids in these configurations, and to distinguish 'true' and 'pseudo' bridging, resulting respectively from non-sister sub-chromatid reunion and from non-sister sub-chromatid reciprocal restitution. Configurations predicted but not seen by Wilson *et al.*, the one-side-arm bridge and the *Y*-shaped chromatid with a corresponding deficient chromatid at the opposite pole, were also found (Fig. 1*b*).

All these configurations, together with the whole chromatid bridges and fragments which also occurred, may be explained as consequences of different patterns of sub-chromatid reunion and restitution. Since most of the configurations require non-sister sub-chromatid breakage or even 3- or 4-strand breakage, it must be inferred that breakage involves the whole chromosome, while reunion is a function of the half-chromatids. The view that the chromosome is the functional unit in breakage is supported by the fact that in all bridges examined the side-arms appear to be of equal length; breakage must have been at homologous or near-homologous points on the chromatids.

Mitotic configurations were similar and included one-side-arm bridges and *Y*-shaped chromosomes. The two-side-arm bridges closely resembled the 'point unions' described by Davidson[7].

To distinguish between the sub-chromatid hypothesis of two-side-arm bridge formation and 'matrix stickiness' as suggested by Östergren and Wakonig[8], irradiated seedlings were transferred to 0·05 per cent colchicine for 24–30 hr. immediately after 108 r. irradiation. If sub-chromatids are concerned in bridge formation, whole chromatid errors should be evident in tetraploid *c*-metaphases. Sub-chromatid reunion, normally resulting in a true two-side-arm bridge, would yield a quadriradial X_2 association composed of a dicentric chromatid and an acentric fragment, while sub-chromatid restitution would yield a quadriradial of normal chromatids. Although only a small proportion of cells showed tetraploid X_2 mitoses after the colchicine treatment, both these configurations were found.

The minimal hypothesis of sub-chromatid structure is that each consists of a single deoxyribonucleic acid (DNA) double helix. Meselson and Stahl[9] have shown that, in replication of DNA, a first-generation molecule contains one original helix and a newly synthesized complementary helix. Taylor *et al.*[6] found a segregation of labelled and non-labelled chromatids in the X_2 *c*-metaphase, but with the existence of half-chromatids (with the minimal single DNA structure) such a situation should not be evident until the X_3 division. It has been shown[10] that there may be a substantial delay either in the penetration or the action of 0·05 per cent colchicine in *V. faba*. This could lead to a mis-identification of X_3 cells as being X_2, because of their tetraploidy.

Taylor's results would be compatible with a quadripartite chromosome, if segregation of labelled from non-labelled sub-chromatids should occur. Relational coiling of sister sub-chromatids would seem to prevent this: if, as seems likely on electron-microscope evidence, more orders of sub-units are present, this difficulty would be further increased. La Cour and Pelc[11] also have questioned the significance of Taylor's work after failing to obtain similar results in a repeat of the experiment: they suggest that colchicine may interfere with replication.

The apparent disagreement of the chromosome duplication studies with the demonstrable half-chromatid structure, as well as the lack of repeatability of the autoradiographic work, indicate that a thorough study of the techniques used in such work is needed before interpretations will be of significance.

PSYCHIATRY

Barbiturates and Eye Vergence

It has been demonstrated[1] that barbiturates influence conjugate eye movements selectively in that they abolish the smooth tracking movements while leaving the saccadic movements intact. Disjunctive eye movements have time characteristics akin to the tracking movements; some effect of barbiturates on convergence has been mentioned[2].

In the following typical experiment a normal subject (age 21, height 6 ft. 3 in., weight 175 lb.) was given 390 mgm. amytal sodium ('Amobarbital Sod.', Lilly) by mouth. Measurements were taken, at suitable intervals over a 12-hr. period, of hetero-phoria with a target at 5 m., of the amplitudes of prism divergence and convergence with a target at

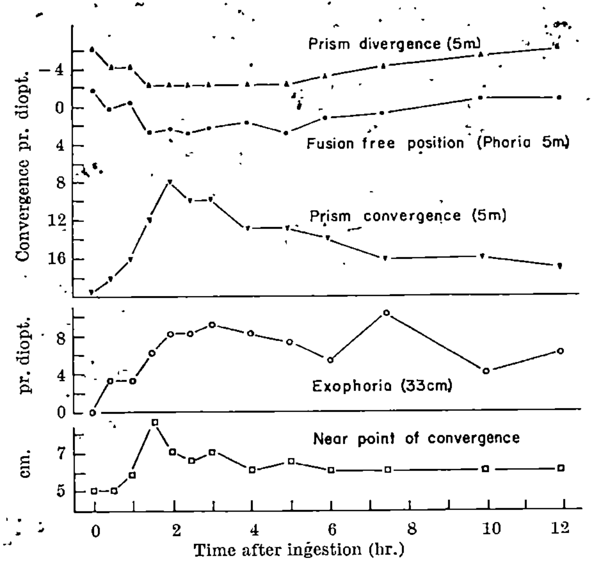

Fig. 1. Changes in a variety of vergence measures following ingestion of 390 mgm. amytal sodium

5 m., of heterophoria at 33 cm., and of the near point of convergence. The changes in the findings are illustrated in Fig. 1. The dose was moderate ; during the phase in which he was most affected (2–6 hr. after ingestion) the subject's ability to make responses was unimpaired, he exhibited only mild barbiturate nystagmus on extreme version of the eyes, and some tracking eye movements persisted. Vestibular nystagmus was unimpaired. The effects illustrated in Fig. 1 were : a change in distance heterophoria in the direction of esophoria, a reduction in the amplitude of the fusional range, a marked change in the near heterophoria in the direction of exophoria, and a recession of the near point of convergence. Experiments with ethanol and anoxia indicate similar effects[3].

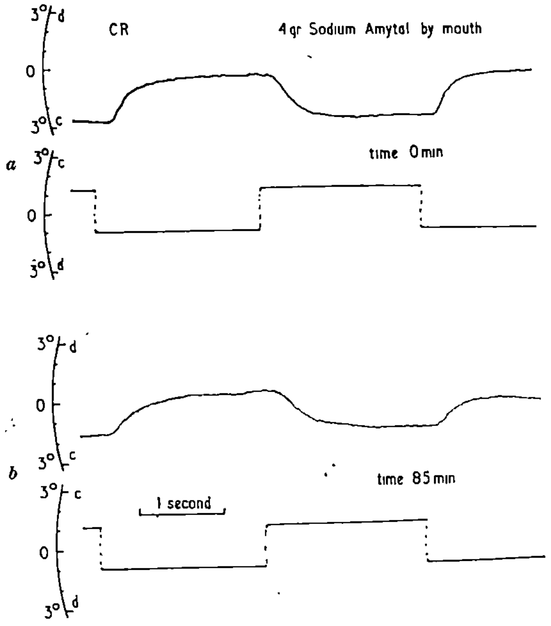

Fig. 2. Eye vergence response to 2° step change in target vergence. (a) Normal state; (b), 85 min. after ingestion of 260 mgm. amytal sodium

To establish whether or not those convergence responses that persisted in the limited fusional range were normal, eye movements records were obtained on one subject with a method described elsewhere[4]. The subject (age 33, height 5 ft. 7 in., weight 135 lb.) was given 260 mgm. amytal sodium by mouth and reached about the same level of intoxication as was demonstrated by the subject in the experiment in Fig. 1. In his normal state when the subject was presented with cathode-ray tubes at 2 m., one in front of each eye, on which spot targets were displaced suddenly so as to need a 2° vergence movement to re-establish binocular fixation, records such as those in Fig. 2*a* were obtained. During barbiturate intoxication the responses looked like those in Fig. 2*b*, demonstrating that, while the final level of convergence reached is the same as that in Fig. 2*a*, the time course of the response is slowed substantially. Records obtained from this subject during this phase showed that he still retains his capacity to make smooth pursuit eye movements during conjugate tracking of sine-waves.

To determine whether the change of the heterophoria at near, which has considerable clinical implications in view of the relatively small dose of the drug involved, could be accounted for in part by a sensory change, we have also measured accommodation. If it does not suffer a deficiency similar to that of convergence, one cannot maintain that the effect of barbiturates is to inhibit in some way the total near response which involves both accommodation and convergence. Measurements of accommodation were obtained by three methods during some of these experiments : (1) the near point of accommodation, (2) the amount of accommodation in play while the subject was fixating the near heterophoria target, using retinoscopy, and (3) the amount of accommodation exerted by the subject during monocular view of a near point target through a semi-transparent mirror, using stigmatoscopy. In each case there was essentially no change in the accommodation measurements throughout the experiment. Neither was there any change in the refractive state for infinity, as determined by retinoscopy.

These findings show that barbiturates interfere with the mechanism which organizes eye vergence movements. This occurs with quite moderate clinical doses which barely affect smooth tracking movements. Saccadic and vestibular eye movements and accommodation responses remain intact under these conditions and this helps to delimit the site of action of the drug.

This work was aided by grant *MY*3034 from the National Institute of Mental Health, U.S. Public Health Service, and by the Institute for Research in Vision, The Ohio State University.

APPOINTMENTS VACANT

Applications are invited for the following appointments on or before the dates mentioned:

Research Fellow (with a good honours degree in a biological subject, some research experience in genetics or preferably cytogenetics, experience in the tissue culture field would be an advantage) to work in the Cytogenetics Group of the Pædiatric Research Unit, Guy's Hospital Medical School—The Pædiatric Research Unit, Guy's Hospital Medical School, London Bridge, S.E.1 (August 25).

Lecturer (Grade II) or Assistant Lecturer (Grade III) in Mycology within the Department of Botany—The Registrar, The University, Bristol 8 (August 26).

Senior Lecturer (with a good honours degree, teaching experience, and either a higher degree or substantial research experience) in the Department of Chemistry, to be responsible for Physical Chemistry—The Principal, College of Further Education, Whitehaven, Cumberland (August 26).

Demonstrator in Psychology, to assist in practical classes and tutorial work—The Registrar, The University, Liverpool, quoting Ref. CV/T (August 28).

Geophysicist (with a degree in science or electrical engineering, and with a knowledge of physics) in the South Australian Department of Mines—The Agent-General and Trade Commissioner for South Australia, South Australia House, Strand, London, W.C.2 (August 31).

Lecturer or Senior Lecturer (qualified to lecture up to honours standard) in Chemistry (Organic or Physical) at Rhodes University, Grahamstown, South Africa—The Secretary, Association of Universities of the British Commonwealth, Marlborough House, Pall Mall, London, S.W.1 (South Africa and London, August 31).

Librarian (professionally qualified and experienced) at the Nigerian College of Arts, Science and Technology, Zaria—The Council for Overseas Colleges, 12 Lincoln's Inn Fields, London, W.C.2 (September 1).

Principal Lecturer (preferably with an interest in the development of research projects) in Pharmaceutics—The Principal, College of Technology, Belfast 1, Northern Ireland (September 1).

Research Assistant (with a good honours degree in botany or agricultural botany and an interest in experimental ecology and/or genetics) in Agricultural Botany, for investigations on the evolution and nature of resistance to zinc and copper toxicity in natural populations of higher plants—The Registrar, University College of North Wales, Bangor, North Wales (September 1).

Research Assistant (with a qualification in chemistry and preferably previous experience in polymer chemistry) in the Isotope Unit, for work in the field of polymer reaction mechanisms—The Secretary, Queen Elizabeth College (University of London), Campden Hill Road, London, W.8 (September 1).

Assistant Librarian (university graduate, preferably with library qualifications)—The Librarian, University Library (University of St. Andrews), Dundee, Scotland (September 2).

Lecturer and an Assistant Lecturer (graduates, with an interest in any of the branches of electrical engineering) in the Department of Electrical Engineering of the Faculty of Science—The Registrar, The University, Manchester 12 (September 2).

Experimental Officer, Grade I (with a degree in physics or equivalent qualifications) at the Weapons Research Establishment, near Adelaide, Australia, to develop optical equipment required for field and laboratory performance testing of lens systems, and to carry out necessary performance testing—The Senior Representative (AV. 120/5), Department of Supply, Australia House, Strand, London, W.C.2 (September 4).

Senior Lecturer, Grade I or II (with a good honours degree and teaching experience, and preferably some research experience) in Mathematics at the Nigerian College of Arts Science and Technology, Zaria Branch—The Council for Overseas Colleges, 12 Lincoln's Inn Fields, London, W.C.2 (September 4).

Lecturer (preferably with some teaching experience and a veterinary qualification) in the Department of Veterinary Physiology, Royal (Dick) School of Veterinary Studies—The Secretary, The University, Edinburgh (September 5).

Assistant Chief Inspector of Nuclear Installations (with a first- or second-class honours degree in engineering or physics, corporate membership of an appropriate professional institution, and wide experience of work on nuclear installations and the management of a team of professional engineers) in the Inspectorate of Nuclear Installations of the Ministry of Power to take charge of sections of the Inspectorate concerned with the safety assessment of nuclear installations, and with special problems in nuclear physics, chemistry, metallurgy and health physics—Civil Service Commission, 17 North Audley Street, London, W.1, quoting Ref. S/5355/61 (September 6).

Assistant (graduate in botany or agriculture or equivalent qualifications) to the Mycologist, for work involving testing the susceptibility to disease of crop varieties, and at present is mainly concerned with the cereals—The Secretary, National Institute of Agricultural Botany, Huntingdon Road, Cambridge (September 15).

Lecturer and a Senior Lecturer in the Department of Medical Biochemistry, Monash University, Clayton, Victoria, Australia—The Secretary, Association of Universities of the British Commonwealth (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia, September 15).

Director of Combined Studies in the Faculty of Science, to supervise admissions to, and the progress of. students in the courses leading to the newly instituted degree in which two science subjects are studied to a higher level—The Registrar, The University, Leeds 2 (September 18).

Senior Assistant Chemist (member of an appropriate chemical institution, extensive experience in large-scale sewage purification and trade effluent control, and preferably with a university degree and membership of the Institute of Sewage Purification) at Mogden Purification Works, Isleworth, Middlesex—The Chief Chemist, Middlesex County Main Drainage Department, P.O. Box No. 7, Isleworth, Middlesex, quoting H.23T (September 18).

Senior Research Fellow or Research Fellow (with a Ph.D. degree in organic chemistry, with additional experience in general synthetic organic chemistry) in the Biological Inorganic Chemistry Unit, John Curtin School of Medical Research, Institute of Advanced Studies, Australian National University, to work on the synthesis of multidentate organic ligands, as part of the programme of the Unit on the effects and utilization of metal complexes in biological systems—The Secretary, Association of Universities of the British Commonwealth (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, September 18).

University Demonstrator (with some acquaintance with population studies and biological statistics) in Physical Anthropology—The Secretary of the Appointments Committee, Faculty of Archæology and Anthropology, The University, Downing Street, Cambridge (September 18).

Senior Lecturer or a Lecturer in the Department of Electrical Engineering at Newcastle University College, University of New South Wales—The Agent-General for New South Wales, 56–57 Strand, London, W.C.2, and the Appointments Section, The University of New South Wales, Box 1, Post Office, Kensington, New South Wales, Australia (September 22).

Experimental Officer or Senior Experimental Officer (preferably with previous experience of high voltage engineering, electronics, and nuclear physics, and a degree or diploma in physics or electrical engineering), to take charge of the maintenance and operation of the Manchester University 6-MeV. electrostatic generator—The Registrar, The University, Manchester 13 (September 30).

Full-time Lecturer or Senior Lecturer in Pathology—The Director, Department of Pathology, Institute of Ophthalmology (University of London), Judd Street, London, W.C.1 (September 30).

Lecturer in Theoretical Physics; a Lecturer in Physics; and Assistant Lecturers in Physics—The Registrar, The University, Manchester 13 (September 30).

Nuffield Foundation Research Fellows (2) (well qualified in electrical engineering or physics with general experience in electronics and considerable detailed knowledge of solid state circuits) in the School of Electrical Engineering, University of Sydney, Australia, to be associated with the development of electrical engineering aspects of the design of a large radioastronomy interferometer system under development by the Radio Astronomy Centre—The Secretary, Association of Universities of the British Commonwealth, Marlborough House, Pall Mall, London, S.W.1 (September 30).

Senior Demonstrator (graduate) in Zoology at the University of Western Australia—The Secretary, Association of Universities of the British Commonwealth (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, September 30).

Lecturer in Applied Pathology—The Secretary, Queen's University, Belfast, Northern Ireland (October 1).

Lecturer/Senior Lecturer in Botany at the University of New England, Armidale, New South Wales, Australia, to lecture in plant physiology or in mycology-microbiology to advanced students in botany and to supervise research projects of postgraduate and final year (botany double major) students—The Secretary, Association of Universities of the British Commonwealth (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, October 6).

Assistant Experimental Officer (with H.N.C. or pass degree, or, if under 22, G.C.E. "A" level or equivalent) in the Physics Department, to assist in studies of physical properties of dairy products—butter, cheese, etc.—and to construct and modify experimental testing equipment in the departmental workshop—The Secretary, National Institute for Research in Dairying (University of Reading), Shinfield, Reading, quoting Ref. 61/4.

Biochemist or Chemist, to study metabolism of ^{14}C-labelled steroid hormones—The Professor of Physiology, The Medical School, King's College (University of Durham), Newcastle-upon-Tyne 1.

Biochemist (qualified), for steroid work in an endocrine laboratory in the Obstetric Unit of the Medical School of University College Hospital—The Secretary, University College Hospital Medical School, University Street, London, W.C.1.

Grade B Assistant to teach Physics—The Principal, Huddersfield College of Technology, Huddersfield.

Graduate Assistant (science graduate, preferably with some dairy experience), to undertake a study of pipeline milking—Head of the Department of Dairy Science, University of Alberta, Edmonton, Alberta, Canada.

Graduate or Technician (A.M.I.L.T.), to assist with research on problems of fibrinolysis in relation to coronary thrombosis, etc., the work will be mainly hæmatological—The Assistant Secretary, Westminster Hospital, London, S.W.1.

Nuffield Research Assistant (with a good honours degree in either physics or a biological science) in Biophysics, to work under the direction of Dr. K. W. Keohane—The Secretary, Chelsea College of Science and Technology, Manresa Road, London, S.W.3.

Postgraduate Student (man or woman graduate with an honours degree in chemistry), for work involving research in boron chemistry—The Principal, Royal Holloway College (University of London), Englefield Green, Surrey.

Research Assistant, to help with current research on an immunological project connected with rheumatoid arthritis—The Pathologist, Stoke Mandeville Hospital, Aylesbury, Bucks.

Research Assistant, to undertake programming investigation in connexion with a second college digital computer now under construction—The Principal, College of Technology, Broadway, Letchworth, Herts.

Research Assistant (with a B.Sc. degree) in the Department of Medicine, to join a small team working in cardio-renal physiology in its relation to human disease—Joint Clerk to the University Court, Queen's College (University of St. Andrews), Dundee.

Research Student (with an honours degree or equivalent qualification, for example, G.R.I.C.) in Electrodialysis, to carry out research for a period of three years under the direction of Dr. P. Meares on fundamental aspects of the transport of ions in charged membranes using radioactive tracers—Prof. G. M. Burnett, Department of Chemistry, The University, Old Aberdeen.

Research Technician (with some experience in a biochemical research laboratory), for work in the Department of Chemistry and Food Technology on chemical and fermentation studies of the cocoa bean—The Secretary, Borough Polytechnic, Borough Road, London, S.E.1.

SENIOR TECHNICIAN (with at least A.I.S.T. or National Certificate), for electron microscope duties in the Department of Zoology—The Secretary, The University, Old College, South Bridge, Edinburgh.

TECHNICAL OFFICER (Utilization) (with a Diploma or City and Guilds Final Certificate in machine wood-working, wood technology or allied subject) IN THE DEPARTMENT OF FOREST RESEARCH, Nigeria, to take charge of one or more sections of the new Forest Products Research Laboratory, including wood-working, seasoning, impregnation and timber mechanics—The Recruitment Attaché, Nigeria High Commission, 9 Northumberland Avenue, London, W.C.2, quoting Ref. 1.2/3.

TECHNICIAN (male or female) IN THE MICROBIOLOGICAL TEACHING LABORATORY—Mr. Edwards, The School of Pharmacy, 29/39 Brunswick Square, London, W.C.1.

GOVERNMENT RESPONSIBILITY IN SCIENTIFIC RESEARCH AND DEVELOPMENT

THE rather rambling debate in the House of Commons on July 10 on science was ostensibly concerned with the supply of services connected with science in the Civil Estimates for 1961–62, covering specifically the votes for the Office of the Minister for Science, Atomic Energy, the Department of Scientific and Industrial Research, the Ministry of Power, the Medical Research Council, the Agricultural Research Council, the Nature Conservancy, the Ministry of Education, the Scottish Education Department, and the universities and colleges, etc., of Great Britain. It is perhaps worth noting that, although referred to in the debate, the Overseas Research Council was not specified in the motion, although Sir David Eccles in particular stressed the vital importance of contributing an adequate proportion of scientists and technologists to the underdeveloped countries. The debate, which was opened by Mr. F. Peart, was, however, directed more specifically at the examination of Government scientific policy in general, and the adequacy of our present organization for determining priorities and formulating the policies needed to-day.

Policies are inevitably determined by the political objectives which are regarded as desirable, and to that extent scientific policy and the strategy and tactics by which policy is executed are influenced also by politics. Provided, however, political considerations are not allowed to overrule or dominate the strictly scientific or technical issues or possibilities, that should not prevent a constructive approach in which party politics are subsidiary, or even the formulation of particular policies on which the support of all political parties can be assured. Some such issues were manifest in the debate itself, but unfortunately, from the outset, party politics were allowed to play a dominating part. Speaking for the Government, the Minister of Education, Sir David Eccles, and the Parliamentary Secretary for Science, Mr. Denzil Freeth, had little difficulty in dealing with the charge of complacency. In consequence, few constructive suggestions were made, apart from those in Sir Hugh Linstead's sound and discerning speech, and the debate as a whole did little to explore the issues as to the relations between Government and science which were recently opened up in the concluding chapter of Sir Charles Snow's book, *Science and Government*. If speakers were aware of the issues which arise out of the relations between the scientist and Government, they made little attempt to discuss them, and the debate merely directed attention to some but not all, of the problems which arise in this field and which require examination before adopting any more definite pattern, or the authoritative intervention in the direction of science which Mr. T. F. Peart advocated and which was also put forward in the Labour Party's pamphlet, *Science and the Future of Britain**.

Broadly speaking, apart from seeking to sustain the charge of complacency brought by Mr. Peart, speakers from the Opposition were concerned to raise specific issues where greater effort appeared to be desirable rather than to elucidate the conditions which might promote greater understanding of the work of the scientist and the contribution of science in public affairs, or even more effective co-operation between the scientist and the administrator. Neither Government nor Opposition spokesmen for the most part noted that the contribution of a scientifically trained mind is a valuable and even a necessary corrective and check on the experience and intuition of the administrator; nor did they note Sir Frederick Brundrett's observation, in the tradition of a remark of Rutherford's that Sir Henry Tizard was wont to quote, that research does not flourish in an atmosphere of luxury but that it is best done when it has to justify itself.

Sir Frederick's remarks in the article which he contributed on "Government and Science" to the *Journal of Public Administration* some five years ago are entirely apposite to-day, and as worthy of note by participants in the recent debate as those of Sir Charles Snow in the book already noted. Sir Frederick was urging indeed greater support by the State for technology rather than for pure science, and pointing to the need which Sir Henry Tizard repeatedly emphasized for the effective use of existing knowledge. He stressed also the importance of direct contact between the research worker and the user, and expressed the view that the results achieved in civil research are not commensurate with the effort expended. Sir Frederick thought, indeed, that in civil research we are not sufficiently critical of the need for research as opposed to the need for applying existing knowledge. He suggested that our defence organization had gone a long way towards finding a proper solution to the problem of the relation between scientist and government, because in that field the scientist had comparatively clear objectives and his place had been firmly established on the policy-making bodies.

Recent moves by the Advisory Council for Scientific Policy have removed a little of the substance of some of Sir Frederick Brundrett's criticism, but it is still probably true that the Advisory Council is not sufficiently supported at lower levels and that its membership could include administrators from 'user' Departments. It is interesting to note how much in line with Sir Frederick's views are the conclusions reached by Sir Charles Snow. He emphasizes the importance of clear objectives and of an appropriate position within the structure of government, permitting of effective touch with working administrators and serving officers—the users—and also with Ministers and the highest Civil servants. He specifies, too, powers of action, but that is in relation to a committee responsible for dealing with a concrete problem: on such a body as the Advisory Council for Scientific Policy he has no specific comment, though he wants scientists to be active in all levels of government, and is as clear as Sir Frederick that the scientific mind has an essential contribution to make in the shaping of general policy.

---

* *Science and the Future of Britain*. Pp. ii+46. (London: The Labour Party, 1961.) 2*s*.

Sir Charles Snow may perhaps accept too readily the need for decisions, especially on technical matters, being made behind closed doors; but that only underlines the importance of the problem, to which Sir Henry Tizard directed attention in his Haldane Memorial Lecture, of ensuring that most of our future administrators, if not all, shall have had a broad scientific education. On one side, Sir Henry suggested, it may be recalled, forming a central scientific staff, engaged only on studying questions of policy, under the immediate direction of the Advisory Council, to which young scientists could be seconded for a year or two from the research establishments, to which they could be transferred back if they had not the necessary qualities for higher administration. On the other hand, Sir Henry lent the full weight of his experience and authority to any measures to ensure that future administrators had a broad scientific education. Sir Frederick has more recently confirmed these views and stressed not only the need for the administrator himself to possess sufficient scientific background to discriminate between the essential and non-essential elements in the scientific aspects of a problem but equally for many departments to include a scientific component as a permanent measure.

Sir Charles Snow's book was not overlooked in the Commons debate. Sir H. Legge-Bourke, stressing the point which Sir Charles Snow made about the contribution of foresight which scientists could make to our existential society, thought that this was one reason for increasing the number of those with scientific knowledge in the Civil Service who might not have any direct scientific responsibilities in most of their work. He was ready to support the argument for bringing in scientists at all levels of government, not to centralize the control of scientific policy, but rather to provide a bridge between the scientific and the political world and to lift our gaze to the horizons that lie ahead. It is essential, he believes, to ensure that at least one Minister has the time to view the whole field of national activity and to contrive ways of ensuring that Ministers, Civil servants, trade unionists, industrialists or others concerned are made aware of the need to consider the right scientific subject. For this reason he thought that the Minister should be the Minister for Science and not of Science, and he also urged that he should not disregard our national characteristics.

Sir Harry Legge-Bourke came nearest to the expression of the views of Snow as well as Brundrett and Tizard, but they also found some expression in Sir Hugh Linstead's speech. Fully supporting the idea of a Minister for Science, he thought the Minister's primary duty should be not to run science but to foster and encourage it independently—so far as may be possible—of the executive Government of the day. Sir Hugh saw the Minister's duty as being to define, on the best advice he could get, the problems on which the resources of the country should be concentrated, making certain that the fallow fields are cultivated, and that over-cultivated fields are allowed to lie fallow. He also believes that the best results would be obtained if the maximum use were made of instruments other than Government organizations, and although Sir Hugh referred to the use of project research, in which a Government Department financed research undertaken by a university on a particular project, he was obviously unconvinced as to the soundness of this technique. He stressed the importance of the Minister and his staff following up by personal contact rather than directive or Ministerial circular, and, having defined the framework and allocated the responsibilities, the Minister should be zealous to leave the scientists their freedom.

The Minister for Science has immense responsibilities; but, in urging that he would discharge those responsibilities best by the least possible use of the great power of his office and by the maximum possible use of its great influence, Sir Hugh took up a position much closer to that of Mr. Denzil Freeth in concluding the debate for the Government than to that of Mr. Peart in opening. The stress laid on the need for executive power on the part of the Minister and for a Scientific and Technical Planning Board, consisting largely of scientists and largely replacing the existing Advisory Council on Scientific Policy, which new Board would become the chief instrument for coordinating scientific activity, is the direct opposite of the present system and likely to lead to bureaucracy rather than freedom. As Mr. Freeth pointed out, with the present Advisory Council composed of scientists, industrialists and some official members, there is no political element in the advice given, or reports presented, to Parliament. Further, the Advisory Council makes scientific and not political judgments, considering the scientific needs of the nation as it sees them, and leaving Parliament to be the judge of policy. Further, the concept of research councils on which this system is based stems from the fact that scientific judgments can only be made by scientists, and the judgments on whether lines of research are worthy of public support are made by scientists familiar with the background of problems. The desirability of any project as part of the national, or international, picture of research is judged by leading scientists and expert laymen acting together.

Mr. Freeth, who himself also stressed the point that money is not necessarily the limiting factor in research, stoutly defended the scientists on the Agricultural Research Council from the charges of indolence levelled at them in *Science and the Future of Britain*. He pointed out also the value of alternative sources of finance for the research worker, and quoted Prof. Herbert Butterfield in refutation of the idea that Government and society should take command over the sciences. The future will not allow itself to be managed in this way. Government and society tend to expect the scientist to serve a utilitarian end, and we should be careful to continue to value science even more than technology. The traditional urbanity of the Government in Britain in respect of university autonomy is of greater long-term importance than is often realized, and Prof. Butterfield maintains that a world that gives science the greatest opportunity possible for autonomous development not only possesses freedom now but also has the promise of more flexible development in the future.

Prof. Butterfield, like Sir Hugh Linstead, was careful to reject the claim that the scientist—as scientist—should be allowed to govern. Science and technology in themselves are insufficient to teach the wisdom necessary for steering the ship of state or choosing educational objectives, or even indicating the proper use of scientific achievements. That much is not implied in Sir Charles Snow's emphasis on foresight: as Sir Hugh puts it, the scientist's place in the political scheme of things is rather as a referee than a player.

It would be unfair not to note that, in this highly constructive speech, Sir Hugh Linstead was also critical of the present balance of effort; but he lent no support to the view that because a certain amount was spent on the Agricultural Research Council or the Department of Scientific and Industrial Research, a certain amount must be spent on the Medical Research Council as well. He did not appear to dispute the Medical Research Council's own view that its present £5 million or so is inadequate, in that no worth-while scheme for medical research is rejected for lack of funds. Moreover, although this view has, in fact, been challenged by Prof. A. Haddow, Sir Howard Florey has emphasized the excessive time which may have to be spent in applying for funds. How far this adequacy of funds is true of biological science in general may be another matter, but Sir Hugh certainly did not accept Mr. Peart's choice of the Medical Research Council as an example of inadequate Government expenditure. He repeated that control of research and scientific effort in the universities and in the industry of Britain cannot be separated from control of the universities and of industry, and that undue extension of the planning and direction of university and industrial activities might dry up the very springs of original research and development we sought to foster.

As already noted, in opening the debate Mr. Peart had pleaded for the creation of a Scientific and Technical Planning Board, which he thought should be the main body to apply science in industry and to stimulate new activities, though he also urged greater use of the National Research Development Corporation, particularly in placing research or development contracts. An interesting speech by Mr. Aubrey Jones also advocated the adoption to some extent of the planning methods of the Soviet Union in science and technology, partly because of the present imperfection of communication in technology on the international plane, and partly because the most significant scientific and technological advances occur as a result of the marriage of scientific disciplines. Highly critical of the effectiveness of the research associations, he strongly advocated the use of civil development contracts, to be chosen deliberately and with strategy, so as to make industrial firms themselves more alert to research and development. He believes the old Ministry of Supply was a far better instrument for this purpose than the Department of Scientific and Industrial Research, and rejected outright the idea of extending the functions of the National Research Development Corporation to production. Instead, he would combine the Corporation with the industrial side of the Department of Scientific and Industrial Research, and make this the industrial and technological nucleus of the Ministry for Science.

Mr. Freeth made no comment on this specific suggestion in concluding for the Government; and he also ignored what was probably the most justifiable criticism advanced by Opposition speakers, namely, the Government's dilatoriness and parsimony in providing some of the conditions for effective scientific work—a responsibility which in fact all the post-war Governments share. Both Mr. S. Irving and Mr. A. M. Skeffington strongly urged a more generous policy in regard to scientific information services, referring to the needs of both the National Lending Library for Science and Technology and of the National Reference Library for Science and Information. Doubts as to the adequacy of the building and plans for the latter were freely expressed at a meeting arranged by the Association of Special Libraries and Information Bureaux on May 9, and the assurances then given by Sir Frank Francis, director of the British Museum, were manifestly unable to remove those fears. The need for more vision and greater generosity in finance and buildings was well put in the debate in the House of Commons by both Mr. Irving and Mr. Skeffington, and although on balance scientists and technologists may well think that the Government came out of the debate rather better than the Opposition on this specific issue, they should lend the strongest possible support to the efforts now being made to secure an adequate expansion of the proposals for the new Reference Library at least. The case for a scientific and technical planning board was perhaps not established, but the need for a continuing review of the efficiency of the whole administrative structure for scientific and technological activities was fully substantiated; this should include the supply of scientists and technologists, as well as technicians and craftsmen, the means of identifying areas calling for research and the fostering of those conditions which best encourage creative and effective work by the scientist. There is obviously still need for much constructive thought as to the relations between science and government, and the part the scientist, as such, should play, and the debate established a large measure of agreement among those who have thought deeply about the issues, independent of party political lines.

SPEECH, HANDEDNESS AND CEREBRAL DOMINANCE

Cerebral Dominance and Its Relation to Psychological Function

By Prof. O. L. Zangwill. (The Henderson Trust Lectures, No. 19.) Pp. vii+31. (Edinburgh and London: Oliver and Boyd, Ltd., 1960. Published for the William Ramsay Henderson Trust.) 10*s.* 6*d.* net.

PROF. ZANGWILL'S book embodies the William Ramsay Henderson Trust lectures, and it is pleasant to note, though he never alludes to the fact, that the object of the Trust is: "The advancement and diffusion of the science of phrenology". It could be argued indeed that the phrenologists are still with us, for there are still plenty of people ready to locate supposed psychological faculties in particular areas of the brain. Indeed, the idea of cerebral dominance and handedness implies some form of localization, if only in respect of the cerebral hemispheres, and Prof. Zangwill's object is to discover exactly what this means. The lectures are largely a summary of the work previously published by himself and his collaborators. As he frankly says, "these studies of speech and handedness unfortunately raise far more problems than they solve". Already, however, we must recognize that there is no clear-cut division into right-handed persons with a dominant left cerebral hemisphere and left-handers with a dominant right hemisphere. On the contrary, "in left-handed or predominantly left-handed patients, the dominant hemisphere as conventionally ascertained is more often the left than the right. Furthermore, left hemisphere dominance may even occur in sinistrals who have always written with the left hand". This has certain implications for the study of aphasia, for there is now evidence that recovery from aphasia tends to be more complete in patients who are left-handed or who have left-handed relatives than in those who are fully right-handed, perhaps because unilateral specialization of the language functions in the brain appears to vary between individuals, being as a rule far more pronounced in right-handed than in left-handed subjects.

Prof. Zangwill goes on to study the significance of these facts for the understanding of specific backwardness in reading and spelling. In 75 per cent of his cases there is evidence of some sinistral tendency in the individual or in his family. Mixed or inconsistent hand preference was common, and uncomplicated dextrality rare. He suggests, also, that so-called specific defects in reading and spelling are seldom present in isolation, and are commonly embedded in a more complex developmental syndrome.

For many years now evidence has been accumulating that even in clear-cut right-handedness there are important differences of function between the right and left cerebral hemispheres, and that the left hemisphere, which is dominant in such people, is not merely a mirror image of the right with the addition of functions concerned with symbolic formulation and expression. Some independent evidence of this has recently been provided by studies of sensory disturbances after penetrating brain-wounds in man (*Somato-sensory Changes after Penetrating Brain Wounds in Man*, by J. Semmes, S. Weinstein, L. Ghent and H. L. Teuber, Oxford University Press). It has been found that sensation of the left hand is more diffusely represented in the right cerebral hemisphere than is that of the right hand in the left. Similar observations have been made in many fields of discriminative activity. As yet these remain isolated observations, and we have not reached the stage at which any broad generalization can be inferred from them. Prof. Zangwill's book is a useful summary of the present state of our knowledge of the relationship between speech, handedness and cerebral dominance.

RUSSELL BRAIN

BACKGROUND TO ASTRONOMY

The Fabric of the Heavens

By Stephen Toulmin and June Goodfield. (Nuffield Foundation Unit for the History of Ideas. The Ancestry of Science, Vol. 1). Pp. 272+14 plates. (London: Hutchinson and Co. (Publishers), Ltd., 1961.) 25*s.* net.

HISTORY of science is at present expanding at university-level so rapidly that lectureships are sometimes left vacant for want of suitably trained lecturers to fill them. At school-level the subject is also expanding, but here another limiting factor is the shortage of suitable books.

The present work is that of a series which will do much towards alleviating the shortage. It is a survey of the interlinked history of astronomy and mechanics from earliest times to Newton, with a further outline bringing the story to the present day. It is to be followed in the next few months by no less than three more volumes, each dealing with a major field of history and philosophy of science. One might feel that a lifetime of teaching and research would alone qualify an author for attempting any one of these volumes, but there is a special urgency in history of science and a worthwhile place for general books which give some inkling of the excitement of the subject.

This *The Fabric of the Heavens* certainly does. It is written with fluency and conviction, and the reader never loses interest. There are, however, many signs of the haste with which it was written—along with the relevant illustrations we find a photograph of the port of Pythagoreon and snapshots of a Greek temple taken from different angles—as well as a number of confusions and serious errors of fact. Thus the authors ascribe the discovery of the planet Uranus in 1781 to John Herschel (born 1792) and quote William Herschel (died 1822) as congratulating Bessel on his discovery of stellar parallax in 1837; yet a philosopher of science like Dr. Toulmin must know John Herschel's 1830 *Preliminary Discourse on the Study of Natural Philosophy*, and in writing their promised *The Flux of Nature* the authors must surely be studying the cosmogony of William Herschel. Samuel Clarke, who in fact believed gravity to be a "connate and original law of all matter . . . We ought no more to enquire how bodies gravitate than how the world began to move" is described as protesting "that some push-and-bang mechanism must eventually be discovered for gravity". Galileo, we are told, "did not study freely falling bodies directly". Copernicus's elimination of the equant is discussed in the context of his general cosmology, although the question does not properly arise until we come to his detailed mathematical astronomy; here the role of neo-Platonism in Copernicus's thought is hopelessly underrated, and although highly disparate issues are involved the authors consider "whether its gains outweigh its losses".

These are but a few of the shortcomings of the book, to which must be added the lack of balance which emphasizes the prehistory of the subject at the expense of its more recent history. There is much that is competently and excitingly written; it is most regrettable that these qualities are not combined with the scholarship that has at last become usual in books on the history of science.

M. A. HOSKIN

CHEMICAL GENETICS

An Outline of Chemical Genetics

By Prof. Bernard S. Strauss. Pp. ix + 188. (Philadelphia and London: W. B. Saunders Company, 1960.) 35*s*.

THIS book grew out of a series of lectures delivered at the Faculty of Medicine in Osaka, Japan. It is meant as a brief account for scientists "who have heard snatches of the recent developments in genetics and find them fascinating". Its six chapters deal with: the genetic control of protein synthesis; the chemical nature of the hereditary material; the molecular meaning of genetic recombination; mutation as a chemical process; nucleo-cytoplasmic relationships; the biochemical genetics of man. A book of this kind need not be profound or original, and this book is neither. On the other hand, it should be clear and readable. On the whole, this book is both. It is, indeed, quite unusually readable and conveys to the reader something of the pleasure the original audience must have felt in hearing an interesting subject treated with ease and enthusiasm. Especially, the first two chapters are excellent reviews of the more purely chemical aspects of modern genetical theory.

In the treatment of strictly genetical questions clarity is less apparent. Dr. Strauss does nothing to destroy the superstition that formal genetics is an esoteric subject, difficult of approach even for scientifically trained minds. A few introductory pages of precise definitions and statements should have been sufficient to lay the genetical ground for the remainder of the book. Instead of this, snippets of genetic information are scattered all through the text, with a singular choice of the complex rather than the simple. Mendel's laws are nowhere explicitly stated, but several pages are devoted to the analysis of ordered tetrads in *Neurospora*.

As stressed in the introduction, such a short account of a vast subject must necessarily be selective; equally necessarily, selection will be subjective. The danger that this may slant the overall picture is not always avoided. This is particularly apparent—at least to me—in the chapters on nucleo-cytoplasmic relationships (where research on *Paramecium* is wholly disregarded), and on mutation. The latter deals almost exclusively with work on micro-organisms; yet even for these it is not correct to say that "selection methods are almost always part of any procedure for the detection of mutations". Formaldehyde, one of the most potent mutagens for *Drosophila*, is not mentioned. The ineffectiveness of purine-9-riboside in some experiments with bacteriophage is stressed; its high efficiency in the production of what appear to be point mutations in barley is not referred to. It is also scarcely fair to imply that only our new concept of the nature of deoxyribonucleic acid has resulted in the realization that "mutation is a chemical process since it presents a definite structural change within a molecule".

Critical appraisal, too, is more apparent in the chemical sections than in the genetical ones, where tentative conclusions—such as lack of mutagen specificity for forward mutations—are too readily presented as established facts. One gets the impression that the author is more at home in chemistry than in genetics and behaves like a well-bred foreigner who reserves criticism for the institutions of his native land. However, to be equally at home in both fields is a rare distinction, and, in spite of its shortcomings on the genetical side, this book can be recommended as an attractive and stimulating introduction to a subject that depends for development on close mutual understanding and co-operation between scientists of many branches.

CHARLOTTE AUERBACH

SOVIET POLAR RESEARCH

Problems of the North: No. 1, 1958

(Translation of "Problemy Severa"). Translated December 1960. Pp. iii + 376. (Translations Section, The Library, National Research Council, Ottawa, 1960.) Subscription price per issue, 7 dollars; Single papers, 1 dollar.

THE availability of Russian scientific literature in English translation has improved greatly in recent years. Scientists in some disciplines can now obtain cover-to-cover translations of the leading Soviet journals on their subject. The position is not as good as this in all fields, of course. One in which Soviet work is pre-eminent is that of polar studies, but here the research worker with no knowledge of Russian has had little help. There is thus good reason to welcome from Canada, the country which has fittingly been most active in preparing *ad hoc* translations of this material, the first English language version of a Soviet polar journal. *Problemy Severa*, a product of the Council for the Study of Productive Forces of the Academy of Sciences of the U.S.S.R., first appeared in 1958, and *Problems of the North* was published by the National Research Council in Ottawa in 1960.

The Soviet journal, of which three issues have appeared up to now, has the widest range of its polar contemporaries in the U.S.S.R.: wider, even, than its title implies, because it does not exclude the south. In the first issue, papers are grouped under the headings oceanology, geography and geology, geophysics, biology, economics, the north abroad, the Antarctic, and miscellaneous reports. The contributions are claimed to be the results of original research, and this is true of most of them (although, following what seems to be common Soviet practice, such results are often published several times over in different journals); but there are also a number of review articles. Certainly the papers in this volume hold much of interest to Western specialists: in particular, those on the movement of floating ice in the Arctic basin, the influence of sea-water temperatures in this connexion, polar wandering, the thawing process in frozen soil, the vegetation of northern Siberia at the time of the mammoth, wild life conservation, and Soviet economic organs functioning in the north. The two subsequent issues have continued to cover as wide a field. No. 4 is not yet out, although long expected, and the delay may be attributable to the transfer of the producing agency from the Academy to the State Economic Council.

The English version has been done well, and for an undertaking of this sort the editors probably deserve as much credit as the translators. The jargon of half a dozen disciplines has been comprehensibly rendered, and although much of the wordiness of the original remains, this is inevitable. The maps are well reproduced, and the half-tone illustrations are as good as the poor originals will permit. One criticism of editorial policy must be made, however. In a work so strongly geographical in tone, it is a pity that neither the transliteration nor the form of place-names is that used at the moment by government map-makers in the United Kingdom and the United States. The user who tries to locate a place in any official gazetteer or map may thus be in difficulties.

WEEDS IN BRITAIN

Weeds and Aliens

By Sir Edward Salisbury. (The New Naturalist: a Survey of British Natural History.) Pp. 384+16 plates. (London: William Collins, Sons and Co., Ltd., 1961.) 30*s*. net.

IN this book, the latest in the New Naturalist series, Sir Edward Salisbury discusses, in sixteen chapters, the weed flora of Britain. Not only does he interpret the nature of weeds, and describe diminishing and spreading species and their association with differing ecological conditions, but he also considers characteristics of individual species, reasons for their survival as weeds and, briefly, their control by herbicides.

The author demonstrates clearly his unique knowledge of weeds in general and British weeds in particular. On many occasions, for example, in the genus *Chenopodium*, the reader is made aware of the several closely allied species forming a related group of weeds, clear line-drawings helping to pinpoint diagnostic morphological differences. Data on the reproductive capacity of many species show unmistakably the hallmark of Salisbury.

The case for detailed studies of the life-history, ecology and physiology of weeds, both for academic interest and for their control, is argued persuasively. Especially pleasing is the emphasis placed on the need for investigations on factors affecting establishment of weeds, a field which, until recently, has had less than its share of attention.

To substantiate his arguments, the author makes liberal use of interesting speculations, and logical deductions, not to mention, when available, up-to-date quantitative data. Indeed, the reader cannot fail to be stimulated by Salisbury's dynamic approach to the study of weeds, but he is left with the knowledge that much research is necessary before the adaptation of weed species to characteristic situations can be explained fully.

A disappointing feature of the book are the sections dealing with the association of weeds and specific ecological conditions. Many species are discussed in these chapters; they are briefly described but there are few diagrams to help in their identification. Several, often isolated, facts are presented in the consideration of species; in some, but by no means all, cases there are suggested control measures. These latter do not fall into any systematic pattern. Indeed, chemical control measures seem to be demonstrated empirically with few principles being expounded; for example, the author states that *Poa annua* is resistant to both 2-methyl-4-chlorophenoxyacetic acid and dichlorophenoxyacetic acid, but so are all Gramineae, and the chapter on chemical control, as presented, is of doubtful value.

There are a few surprising statements. For example, Salisbury considers *Allium vineale* more a grassland than an arable weed of heavy land, while bare fallowing is scarcely its most effective control measure. Exception can be taken to the use of common plant names. Some, for example tinker-tailor grass, are not only unaccompanied by specific names but are far from common; others, for example hungerweed and mousetail grass, are much less widely used to describe *Alopecurus myosuroides* than the unquoted synonyms blackgrass and slender foxtail.

In spite of these criticisms the book, containing some 150 references covering many subjects, will be as thought-provoking to the research worker as it is stimulating to the naturalist.

Alec Lazenby

PALÆOGEOLOGICAL MAPS

Palæogeologic Maps

By A. I. Levorsen. (A Series of Geology Texts.) Pp. viii+174. (San Francisco and London: W. H. Freeman and Company, 1960.) 43*s*.

THIS stimulating book deals not only with palæogeological maps in the strict sense but also with palæostructural, palinspastic and 'worm's eye' maps. These maps are quite easy to construct if the stratigraphical data are available; consequently the introductory chapters are short and the greater part of the book is devoted to their interpretation. To demonstrate the kind of information that can be extracted from these maps, about one hundred have been selected of areas ranging in size from a few square miles to whole continents. The maps have been well chosen and are clearly reproduced, the accompanying explanations are lucid and the deductions logical. Among the numerous uses that the author lists for these maps, the most important seem to be to distinguish between sedimentary and structural basins, to separate the structural effects of superimposed fold movements, to locate buried outcrops and to indicate the sources of ancient sediments. In one section the principles are applied to the problem of continental drift and clearly point against the conventional reconstruction of Gondwanaland.

It is disappointing to the British reader that by far the greater number of examples are chosen from North America. This is understandable in an American book, and in any event the technique is more suited to areas that have not been strongly folded. Nevertheless, of several good palæogeological maps published of British areas, the author selects only Buckman's map of the Cotteswolds, probably the first of all such maps. It is, evident, however that much more could be done in Britain along the lines developed in the book—perhaps with surprising results.

Study of the maps presented should provide excellent exercise for students at all stages and they are fortunately arranged in a graduated series. Their full appreciation requires an understanding of the four-dimensional scope of geology.

C. Downie

Commonwealth Universities Yearbook 1961

A Directory of the Universities of the British Commonwealth and the Handbook of their Association. Pp. xxxi+1590. (London: Association of Universities of the British Commonwealth, 1961.) 84*s*.; 13 dollars.

THIS edition of the *Commonwealth Universities Yearbook* is the thirty-eighth since it was first published in 1914. The Association of Universities of the British Commonwealth, which is responsible for the compilation of this directory, feels that "it should not only cover the principal features of each university but should also give accurate and up-to-date lists of members of the university teaching profession in each country of the Commonwealth". In 1,590 pages, including an index of more than 40,000 names, it does that and more, since it includes the universities in the Republic of Ireland, which are not actually in legal membership of the Association.

The continued expansion of systems for higher education has necessitated an 80-page increase in the length of this book as compared with its predecessor, and three new University Colleges (Fourah Bay College, the University College of Sierra Leone; the University of Nigeria at Nsukka; and the University College of Sussex) have been introduced this year.

In the preface, the editors state that due to a great deal of staff movement among local universities, and from one country of the Commonwealth to another, it is only by constant and complete revision that these lists can be made to serve the purpose of identifying particular teachers and research workers. However, the introduction in this issue of some notes on academic salaries, giving salary scales for different grades of staff at the various universities, may only serve to make the editors' task even more onerous in the future.

Journal of Helminthology

Supplement in Honour of R. T. Leiper on the occasion of his 80th Birthday, 1961. Pp. xxii+229. (London: London School of Hygiene and Tropical Medicine, 1961.) 30*s*.

THE eightieth birthday of Prof. R. T. Leiper, emeritus professor of helminthology in the University of London, has been celebrated by the issue by the *Journal of Helminthology* of this special supplement. The knowledge that Prof. Leiper is still actively at work will bring pleasure not only to the many biologists and medical men who have worked with him or have otherwise benefited from his kindly interest and help but also to many others who know or have admired his outstanding contributions to biology and medicine. These are discussed in this volume by Sir Philip Manson-Bahr, the late Sir Ian Clunies-Ross, Prof. B. G. Peters and Prof. T. W. M. Cameron. These contributions are so well known to parasitologists all over the world that they need no further comment here. Prof. J. J. C. Buckley and Dr. L. M. Russell write of Prof. Leiper's other activities, epitomized by his membership, or honorary membership, of many scientific societies and Government bodies, and of his long association with the London School of Hygiene and Tropical Medicine and the part he played in its development. A feature of this volume which will interest many is the record, covering eight pages, of the signatures of many of Prof. Leiper's pupils and associates. It will, one hopes, be a major source of satisfaction to Prof. Leiper that he has, as this record shows, taken, in one way or another, so many distinguished scientists under his wing; and the student of what is called graphology will no doubt find in these eight pages much to interest him and perhaps to refute the confident pronouncements in those engaging books which profess to deduce our characters from our battles with such pens as modern industry provides.

The rest of this interesting volume is occupied by 29 original papers contributed by leading parasitologists of many countries, so that the volume is, in addition to being a tribute to Prof. Leiper, an important issue of the *Journal of Helminthology*.

Prof. Leiper's appointment, on his eightieth birthday, as active consultant helminthologist to the Commonwealth Bureau of Helminthology, which he directed so efficiently for thirty years until his retirement in 1958, will ensure, all parasitologists will hope, that the highly experienced staff of this organization will be able to continue the invaluable work on which parasitology all over the world has for so long relied. No other Commonwealth organization could do this essential work so well. G. Lapage

Stochastic Population Models in Ecology and Epidemiology

By Prof. M. S. Bartlett. (Methuen's Monographs on Applied Probability and Statistics.) Pp. x+90. (London: Methuen and Co., Ltd.; New York: John Wiley and Sons, Inc., 1960.) 12*s*. 6*d*. net.

THIS small book by Prof. Bartlett is the fourth in the series of Methuen Monographs on Applied Probability and Statistics (edited by Prof. Bartlett), the series as a whole being intended to provide inexpensive introductions to the rapidly expanding field of applied probability and statistics. The book concerns itself with probabilistic models as they may be encountered in ecology and epidemiology, and does not attempt to deal with the extensive applications of probability in genetics. A sound basic knowledge of probability is certainly a necessity to appreciate the ideas discussed.

There is an introductory chapter dealing with the role of statistical theory in biology and the relevance and prognostic value of stochastic models. The next chapter deals with some of the well-known statistical distributions (Poisson, negative binomial, logarithmic) which are set up through probabilistic continuity arguments, and introduces basic ideas to encompass spatial distributions. The middle chapters are concerned with deterministic and stochastic models for the period to extinction (or equilibrium state) in populations subject to 'birth-and-death' processes and in which there may be competition, consideration being given to continuous and discrete mechanisms. The closing chapters give an account of models for recurrent epidemics, including the case where the spatial aspect is important and relevant. The basic stochastic models are in general complicated; nevertheless some assessments of the average association between weekly notifications and time to extinction are given in the case of measles epidemics.

The printing is good, the format is attractive and the price is reasonable.

A good deal of the monograph impinges on research which has been carried out in the past few years, a large share of this being due to Bartlett. It should be of considerable interest to ecologists and biologists, and there can be little doubt that every serious student of statistics should possess a copy.

METABOLIC STABILITY OF BODY CONSTITUENTS

By DR. A. N. DAVISON
Department of Biochemistry, Guy's Hospital Medical School, London, S.E.1
AND
DR. J. DOBBING
Department of Physiology, London Hospital Medical College, London, E.1

THIS article is concerned with an appraisal of some modern views on the collective metabolism of body constituents *in vivo*. Many of these ideas have already been expressed by other authors[1–4], particularly in the field of protein metabolism, and will be to that extent familiar. However, acceptance of the concept of metabolic heterogeneity has not always been accompanied by an appreciation of the influence of such ideas on the design of experiments. For this reason it was decided to state a simple working hypothesis, embracing the metabolism of body constituents as a whole, and to stress its influence on both the design and interpretation of metabolic experiments *in vivo*.

The widespread use of isotopes in biological research, which began rather more than twenty years ago, led to the demonstration of a number of important phenomena which had hitherto remained undetected by classical methods. Among these, perhaps the most striking was the discovery of the dynamic state of body constituents, prominently expounded by Schoenheimer[5]. Until this time, the metabolism of body constituents was generally thought to be divisible into two groups in the sense (for example) of the hypothesis of Folin[6] for the metabolism of proteins. Body constituents were either to be considered as structural, and therefore stable, or metabolic fuel, and therefore labile. Added to this was the concept of 'wear and tear' on structure accounting for a relatively small loss from this source and an equally small replacement. The storage of some energy sources in depots was also appreciated.

With the use of isotopes came the demonstration that even the constituents of some anatomical structures appeared to be in an extraordinarily rapid and free dynamic state. Constant rapid synthesis and degradation was postulated as the means by which body structure was held in its apparently static state, and even in such conditions as starvation, when the relative failure of the synthetic side of the equilibrium resulted in net loss of body substance, there was still demonstrable synthesis taking place.

These new revelations led to a general rejection of the older views in favour of the more acceptable hypothesis that the apparent heterogeneity of behaviour of body tissues concealed a hitherto unsuspected activity in all of them. In metabolic terms, this meant both structural constituents and 'fuel' were undergoing dynamic metabolism. The 'fuels' were as labile as had always been thought, but there was also a similar lability of the components of anatomical structure. Research workers began to base their thinking and the design of their experiments on the assumption of the dynamic state of all body constituents. In the field of experimental pathology it was widely suspected that the degeneration of structure in such degenerative conditions as, for example, disseminated sclerosis, might be the result of an imbalance of the equilibrium. Such assumptions have profoundly affected the direction taken by many experimentalists in their investigations.

However, even from the earliest times in the history of metabolic work using isotopes, there have been results which have challenged the simplicity of the new idea. Almost from the outset it was realized that although bone calcium and phosphorus were to a large extent in equilibrium with the body fluids, there was nevertheless a proportion of bone constituents which was apparently metabolically inert[7]. This inertness did not depend on the nature of the substance, since both calcium and phosphorus were at the same time labile and stable in the same tissue. It was therefore assumed that the observed degree of stability represented those constituents which were buried deep in the apatite crystals and were, for these mechanical reasons, inaccessible to the blood stream. In other tissues, notably in the case of muscle-protein, collagen and later of deoxyribonucleic acid in some situations, it gradually became clear that the lability of body constituents was not uniform and that some of them 'turned over' much more slowly than others. The important results of Thompson and Ballou[3], appearing under the title of "The Predominantly Non-Dynamic State of Body Constituents", summarized a growing impression that there was a considerable range of rates of metabolic activity throughout the body. It was even suggested that in the unique case of collagen, the constituent proteins were turning over so slowly that their biological half-life exceeded the life-span of the animal.

As a result of these observations it became clear not only that the metabolic activity of body constituents was heterogeneous, but also that the different organs were themselves heterogeneous in the relative proportions of highly active and less highly active components they contained. The liver was the best example of a tissue which was predominantly highly labile; tendon was at the opposite end of the scale, consisting, it was suggested, predominantly of materials which turn over very slowly; and all other tissues and organs could be arranged in order between these two according to the proportion of their constituents which were stable.

The very important question now arises whether there are body constituents which can be demonstrated to be absolutely inert and have no metabolic activity whatever. This state of complete inertness could possibly be suspected in collagen, at least in some parts of the body, both from the experimental evidence already available and from the very nature of the tissue and its relatively poor blood supply. However, the evidence for absolute inertness is in fact just as good for deoxyribonucleic acid even in such relatively active tissues as liver[8,9], and this is altogether more unexpected on the basis of the older hypotheses.

It is also important that the degree of metabolic stability should be considered in relation to the duration and conditions of any particular experiment. Thus, in a 4-hr. experiment, a given constituent or some proportion of it with a biological half-life of months is relatively stable; whereas in an experiment extending over a year the same constituent may be regarded as metabolically active. While absolute metabolic inertness is admittedly extremely difficult to demonstrate, such stability would have an extremely important influence on the design and interpretation of metabolic experiments. This article is therefore concerned with stating a working hypothesis which assumes an infinite heterogeneity in the metabolic activities of body constituents, amounting to complete and absolute inactivity of some of them; and in the application of this hypothesis to some recent observations on metabolic behaviour *in vivo*. It will be convenient to enunciate its main features and some of its implications in general terms before proceeding to discuss some of the evidence in its favour.

Hypothesis of Infinite Metabolic Heterogeneity

The basic principles of the hypothesis are as follows:

(1) The metabolic behaviour of all tissue constituents can be arbitrarily divided into two main types, present in varying proportion. These are the non-structural components involved in metabolic processes on one hand, and structural components on the other.

(2) The first group, henceforth referred to as the metabolic constituents, are heterogeneous with respect to their metabolic activities. There is a very wide range of turn-over rates to be found among them. Some of the shorter half-lives may be even shorter than can be measured by contemporary techniques; and some of the less-active members of the group are turning over so slowly that, for all practical purposes relative to the life-span of the animal, they may merge imperceptibly with the members of the second, absolutely stable group.

(3) The factors that decide to which group any given substance belongs in any particular tissue are only in a very limited sense dependent on the chemical identity and properties of that substance. Indeed, the same substance can belong, in varying proportion, to both groups in the same tissue.

(4) The relative proportions in which a single chemical substance is distributed between the two main compartments in any tissue will be decided by such factors as the nature and function of the tissue, its state of maturity, and its metabolic state which may vary considerably from time to time even in the adult animal. The chemical properties of a substance may often play a subordinate part in influencing this differential distribution.

If this hypothesis be accepted, a number of important consequences emerge, and these will now be discussed.

Consequences of the Hypothesis

The structural constituents in these terms will never exhibit any metabolic activity. They will be built up in incremental fashion into anatomical structure during the process of growth, and, once incorporated, will remain in that structure as long as it survives. This aspect of complete metabolic stability must be considered on a sub-cellular plane at first, but in those tissues such as the central nervous system, consisting of cells which are not normally renewed during adult life, there is likely to appear some complete stability at the higher tissue-level. Even the most labile epithelial cell which is constantly being lost and renewed contains structural components which are absolutely stable within the lifetime of that cell. The impression of turn-over of structural components of such labile whole tissues will be spurious and will simply represent the rate of loss and regeneration of cells which in the above sense contain stable structure.

Structural stability would, according to this hypothesis, be absolute at all times, even during the course of incremental growth. In those cells and tissues which develop over an extended period of time each molecule, as it is laid down in structure, would be permanent and stable, its persistence there only being restricted by the survival-time of the structure concerned. The principal effect of growth will be on the relative sizes of the metabolic and structural compartments, and it may even be incorrect to consider growing tissues as exhibiting greater turn-over (see below).

Structural metabolic stability will be determined only in a limited sense by the intracellular or extracellular location of the anatomical unit concerned. While it may be true that extracellular matrices such as collagen, inorganic and organic matrix of bone and myelin sheaths are likely to be metabolically stable because of their extracellular position, and while intracellular, cytoplasmic constituents may be largely members of the metabolically active functional compartment, nevertheless important exceptions make it necessary to avoid such misleading concepts as are implied in the expressions 'extracellular structure' and 'intracellular fuel'. The apparent stability of deoxyribonucleic acid and the obvious lability of many constituents of body fluids are the most notable exceptions.

Growing Tissues

One important application of this hypothesis concerns the widely held belief that the turn-over of body constituents is faster in developing animals than in the adult. It is well known that many body constituents appear to turn over to a greater extent in young developing tissues than in the adult when turn-over times are calculated from rates of uptake of precursor. However, it is possible that this apparently greater turn-over may only reflect the influence of incremental growth on the total uptake of a substance, a factor which may play no part in the total uptake into mature, fully developed tissues. In the case of such substances as phosphate, for example, which play a prominent part in both labile metabolism and permanent structure, it is clear that some of the high total uptake into some developing tissues may be ascribed to incremental growth of a structural compartment which, as it is laid down, may thereafter remain inert. This is not to deny the possibility of increased turn-over in the metabolically labile compartments of young animals; but any claim that young tissues have a more active metabolism than old tissues must take the influence of this increasing size of the structural compartment into account.

The theoretical criteria which must be satisfied before turn-over times may be calculated from rates of uptake of precursor into product have been appreciated for many years[10-12], but this has not prevented their unfortunate and imprecise application to highly complex biological systems, in which such rigid criteria can rarely be satisfied. If the entry of a metabolite into a developing tissue be considered partly in terms of entry into inert structure and partly into a labile metabolic compartment, it is clear that no valid estimation of turn-over rates will be possible by extrapolation of rates of total uptake. The assumption by some workers that, following a single dose, the rate of loss from a tissue will be a mirror image of the rate of entry, is often unwarranted, since it implies metabolic homogeneity of that substance in the tissue. Furthermore, any results in terms of specific activity are inevitably misleading. This is due to the fact that the specific activity expresses radioactivity per unit weight, including metabolically inert as well as labile substance in the denominator of the expression. The specific activity is therefore reduced or 'diluted' by any quantity of metabolically inert material present. The specific activity will be diluted to a varying extent, changing especially during development, and this will greatly complicate comparisons of old and young. The same artefact of expression will also have the effect of depressing the apparent rate of entry into tissues, and the greater the size of the inert compartment (as in the adult), the greater will be the apparent depression of these rates of entry. This point also has important general implications for work on blood-tissue relationships such as the 'blood-brain barrier'[13], in tissues where the proportion of inert constituents is high.

Before leaving the topic of the complicated metabolic differences between old and young tissues, it must be stressed that there are circumstances in many adult tissues which are analogous to those in the developing animal. Cells were originally classified by Bizzozero on the basis of the degree to which they have preserved the power to divide by mitosis into post-natal life. 'Labile' cells, which normally continue to multiply, and 'stable' cells which retain the capacity for mitotic division are to be distinguished from 'permanent' cells which lose this ability at about the time of birth. Tissues containing cells of the first two types are likely to show an apparent metabolic activity on the part of their structural components which may simply be due to the loss of whole cells and their replacement by regeneration. Inasmuch as regeneration is taking place in a tissue, to this extent there will be an apparent turnover of structural components. The structural constituents of the cells concerned will, on the basis of the present hypothesis, be metabolically inert, the inertness being limited only by the life span of the unit to which they belong. A special example of this is to be found in the proteins of the evanescent red cell[14,15]. There is, in this way, a metabolic analogy between regenerating tissue, normal or otherwise, neoplastic tissue and the normal developing animal. The truth of the analogy is often obscured by a failure to appreciate its basis in the varying life-span of morphological structure.

Implications for the Design of Metabolic Experiments

If the above hypothesis and its theoretical implications be accepted, it must follow that metabolically inert morphological structure can only be labelled during the course of its growth and development, either in the developing animal, or, in the case of regenerating tissues, during regeneration. In the case of the central nervous system, for example, the structural compartment presumably consists mainly of the myelin sheaths, and these must therefore be labelled in the course of myelination or not at all. The period of development during which inert structure can be labelled naturally depends on the tissue and on the species.

Incorporation of calcium, which is to become part of the inaccessible calcium compartment of adult bone, will occur only during the development of that compartment. Moreover, in the adult rat, the epiphyses of which never fuse, and the skeleton of which is therefore always 'developing', a different general picture will be seen from that in the human and other species which normally achieve a state of maturity in which there is little further incremental growth. The process of remodelling of adult bone blurs the distinction, and a new situation analogous to early development arises during repair. It is not known to what extent normally inert calcium leaves the skeleton under the many disturbed metabolic conditions of decalcification because, at present, experimental methods have not successfully distinguished in this case between inert and labile compartments.

Myelination of the rat central nervous system begins about ten days after birth, and is virtually over when the animal is seven weeks old; thus it is only during this period that labelled substances can be incorporated into the lipids and protein which make up the sheath. The baby guinea pig is virtually fully myelinated at birth, and similar incorporation in this species could only be accomplished in the fœtus. However, the situation is greatly complicated by the fact that constituents of the myelin sheath are not unique to that structure, and none is known which does not to some extent also take part in the metabolic activities of the brain. Therefore, although myelin may be labelled during myelination, every label will to some extent also enter the metabolic compartment; and until sufficient time has elapsed to allow the dynamic turnover to dispose of this labile portion, the extent to which label is incorporated into inert structure will be obscured. The length of time required to lose cholesterol labelled with carbon-14 and phospholipids labelled with phosphorus-32 from the metabolic compartment of the brain following single-dose administration during early life is at least five months after injection, and it is not until this labile material has disappeared from the total radioactivity that the metabolic inertness of the labelled structure is revealed.

Since experiments are usually performed on adult tissues, and for much shorter periods than this, it is not surprising that direct labelling of inert structure has only recently been demonstrated. Metabolic inertness can, however, be inferred or suspected in much shorter experiments from the failure to label such structures as these in adult tissues. Since nearly all the cholesterol in adult brain is in metabolically inert structure, it has been suspected for a long time that the failure of labelled cholesterol (or of labelled precursors) to enter adult brain might be due to the metabolic stability of this lipid in this organ. However, widespread misconceptions over the nature of the 'blood-brain barrier' were more readily available as an explanation, and it required the direct demonstration of inertness by means of the long-term experimental design mentioned above to provide the first direct evidence. Recently, it has been demonstrated that cholesterol labelled with carbon-14, given either as the intact lipid[18] or as a suitable precursor[19], can indeed be incorporated in small quantities into the central nervous system. This labelled cholesterol undergoes very slow turnover and on the basis of the present hypothesis may be taken to represent a small pool of metabolically active cholesterol. Myelin sheath cholesterol is, of course, only one example of a structural constituent of a tissue the inertness of which has been demonstrated by an experimental design of this kind. Other examples include the bone minerals[7,20], deoxyribonucleic acid in non-dividing cells[8,9], the glycine incorporated into collagen[21] and some of the structural proteins in muscle[22].

Single-dose Experiments

Experiments involving the single-dose administration of a precursor of a tissue constituent during the course of that tissue's development produce the kind of result illustrated in Fig. 1. The values of the ordinate are better expressed in terms of the anatomical unit when growing animals are being used, a device which avoids complications of the single-dose experiment due to incremental growth progressively diluting the labelled constituent. The fate of injected precursor can be considered in two phases. During the first (phase *A*), the gradual incorporation into a structural compartment is added to the amount taken up more rapidly into the metabolic compartment. The latter, however, has a finite biological half-life, and towards the end of phase *A* most of it has been lost. It is not until this loss is virtually complete that the structural, metabolically stable material is revealed (phase *B*). In most cases, phase *A* lasts several months. The two phases must also overlap considerably for a very long time, during which interpretation will be exceedingly difficult. A semilog plot helps to distinguish some of the grossly different components of the curve and could in some circumstances also lead to an estimate of compartment size[3].

It can also be seen that a mean turnover-rate in a heterogeneous system calculated only from rates of uptake is likely to be meaningless and often misleading. Metabolism can then only be properly investigated by prolonging the experiment to describe directly the rate of loss as well as the rate of incorporation. There is virtually always a serious restriction, therefore, on the value of *in vitro* experiments for these purposes. Even when the 'surviving' tissues are from adults, and particularly when they are from young animals, few remain viable long enough to follow the loss of incorporated label which is likely to be much more prolonged than the period necessary for uptake. An exception to this general limitation on the value of *in vitro* experiments might be found in tissue culture, the employment of which for these purposes has scarcely begun.

A further complication of *in vivo* metabolic experiments is the varying relationship between the changing blood-levels of labelled precursor and the amount of isotope in the tissue. Thus phosphorus-32 persists in the blood for at least two months after injection into neonatal rats, and considerably longer in adults[17]. Similarly cholesterol labelled with carbon-14 remains in the blood for a month after injection into day-old chicks[23]. This effect corresponds to a continuous perfusion of precursor, and in this way label may enter compartments of low metabolic activity. This could account for the slow and very small incorporation of [4-^{14}C]-cholesterol into the adult central nervous system and for the very slow loss of labelled sterol thereafter (Fig. 2).

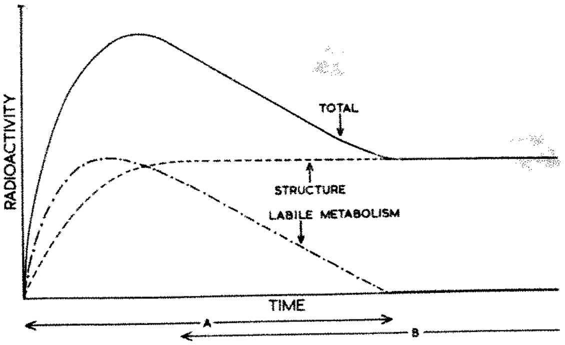

Fig. 1

Multiple-dose Techniques

The usefulness of single-dose experiments *in vivo* is, however, severely restricted in other ways which have been appreciated almost since the first use of isotopes in biology. The level of label at any time after injection is the resultant of so many metabolic processes, each of which has such a variable influence at different times, that meaningful interpretation is often impossible. One of the most variable factors is the size of the precursor pool being presented to the tissues in the early stages, since it usually drops precipitously soon after administration. The fall is due to equilibration with extracellular space, excretion and the preferential uptake which sometimes occurs rapidly into certain special tissues. Various techniques have been devised to overcome the difficulties of single-dose experiments by achieving a constant level of labelled precursor. This may be artificially accomplished by mathematical correction of the level of label in the product to the level in precursor at the same point in time, the ratios of product to precursor often being referred to as relative specific activities. Alternatively an attempt may be made to keep the precursor constant by repeated injection for a prolonged period until all active constituents have become equilibrated with it. Administration is then stopped, and the rate of loss of label studied. The mathematical correction to relative specific activities may be very misleading when slow synthetic and degradative processes are being studied in an animal in which precursor values are changing rapidly, and this is usually particularly the case in the period immediately after injection[24]. Another difficulty is that the relationship can only be calculated if the immediate precursor is known[10,12]. Rates of change of relative specific activities become even more difficult to interpret when the product in the numerator is metabolically heterogeneous in its relationships

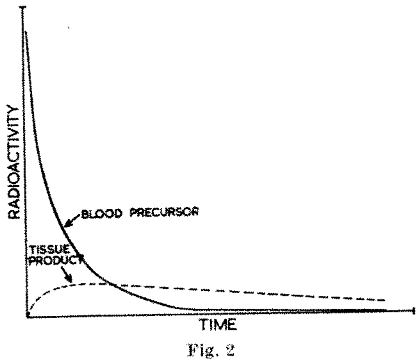

Fig. 2

with its precursor: that is to say, when there is a heterogeneity of turnover-rates of a substance in the different metabolic compartments of the same tissue.

A much more useful technique for investigating heterogeneous metabolism *in vivo* is that employed by Thompson and Ballou[3]. They exposed rats to tritiated water from the time of conception, by repeated administration to the mothers before and throughout pregnancy and lactation. Even after weaning, the water supply was constantly labelled, and so, when the animals were mature, they had presumably incorporated tritium fairly evenly into most body constituents. At this stage, tritium administration was stopped, and the rate of decline of tritium in different tissues and tissue constituents was studied for many months. Components of the biological decay curves were identified, extrapolated backwards, and the sizes of different compartments as well as their biological half-lives estimated. This design of experiment is capable of very great biochemical and physiological variation, and its extension would yield many important quantitative data concerning metabolically heterogeneous compartments. It has many advantages over the single-dose *in vivo* experiment for these purposes.

Areas consisting of inert structure can sometimes be separated from others predominantly containing rapidly metabolizing cells owing to the anatomical arrangement of some tissues. For example, brain white matter and grey matter can be crudely separated, and although there is no complete division into neuronal cells, glial cells, and myelin sheaths, significant metabolic differences can be studied which are partly based on the relative amount of inert structure present[16,25]. It is far more useful for many purposes to dissect brain this way than to separate it into brain stem, cerebellum and cerebrum. A similar gross separation is quite impossible in the case of the more homogeneous tissues like liver. However, differential centrifugation offers further possibilities of separating the different anatomically based components of tissues[26,27]. By these means it is possible to obtain information separately about the different roles of the same substance within the same tissue, and about the infinite range of metabolic rates involved.

Conclusion

A revolution occurred twenty years ago as the result of the application of isotopes to biological research. A new generation of thought quickly adopted the doctrine of the dynamic state of body constituents. In the past two decades, however, the new doctrine has been substantially modified by an increasing appreciation of the wide range of rates of metabolism taking place in tissues. The realization that the same material may be metabolized at different rates in the same tissue, and that many important tissue constituents may even be metabolically inert, has come relatively recently. This new evidence has been only slowly recognized by those who have already accepted that all body constituents engage in the dynamic equilibrium. An awareness of the concept of extreme and even infinite metabolic heterogeneity is necessary to a more complete understanding of tissue metabolism *in vivo*, and without it, it is not possible to make meaningful comparisons between different tissues, or between the same tissue at different stages of development. It is suggested that much that is puzzling about existing results may become clearer in the light of these new ideas. They should be considered in any investigation of *in vivo* metabolic turnover problems in the future.

AFRICA'S FIRST SCIENCE MUSEUM

By MURRAY SCHOONRAAD

South African Council for Scientific and Industrial Research, Pretoria

ON August 26, 1960, Dr. P. J. du Toit, F.R.S., former president of the Scientific Council in Africa South of the Sahara, opened Africa's first Science Museum in Pretoria. The Permanent Exhibition of Modern Science was established under the auspices of the Pretoria Centre of the South African Association for the Advancement of Science to commemorate the Union Festival 1960. It has been arranged in the form of an exposition of contemporary science in which that in South Africa is seen against the background of world science. Its aim is not only scientific but also to demonstrate agricultural, mining and manufacturing processes; for to-day's science is to-morrow's technology. Furthermore, this will serve as an institution where the noteworthy achievements of South African scientists could be explained and their original instruments and equipment preserved for posterity.

R&D

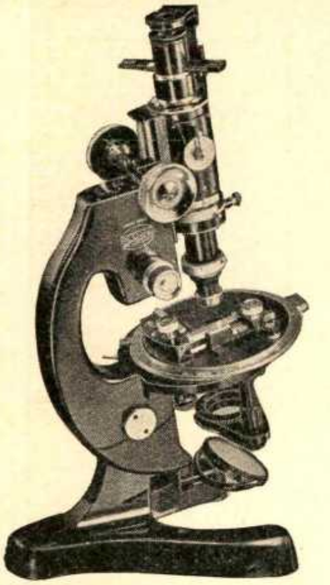
A new monthly technical magazine for the 103,000 scientific workers engaged in research and development

Although there may be little common ground between the products of one industry and another the techniques of research and development are universal. It is the purpose of 'R & D' not to report the results of research programmes but to pass on useful information about the means by which results were obtained—in short, to assist the cross-fertilisation of scientific ideas in the field of research and development.

In addition to information about new methods and new techniques, 'R & D' will provide details of new equipment and apparatus as it comes on the market and which forms no small part of the £655 million which it is estimated will be spent on research and development this year. 'R & D' has already had the co-operation of many of the research associations, of independent sponsored research organisations and of the research and development departments of many great companies.

'R & D' is available to bona fide scientists, engineers and technicians engaged in research and development on payment of an annual registration fee of 10/- (12 issues post free). Applications for registration together with the remittance for 10/- should be sent to the Circulation Manager, 'R & D', Tower House, Southampton Street, London, W.C.2.

No. 5000 PETROLOGICAL MICROSCOPE



Advanced student type of highest quality and workmanship.

Incorporating modern features.

Please write for full particulars.

R. & J. BECK LTD.

69/71 MORTIMER STREET, LONDON, W.1

Manufacturers of high grade microscopes for more than a century

This quarterly journal of instrument engineering contains information of latest developments. It is available post free on request—ask to be put on the mailing list.

MUIRHEAD & CO. LIMITED, Beckenham, Kent, England. *Telephone: Beckenham 4888*
MUIRHEAD INSTRUMENTS LTD., Stratford, Ontario, Canada. *Telephone: 271-3880*
MUIRHEAD INSTRUMENTS INC., 441 Lexington Ave., New York 17, N.Y., U.S.A. *Telephone: Murray Hill 2-8131*

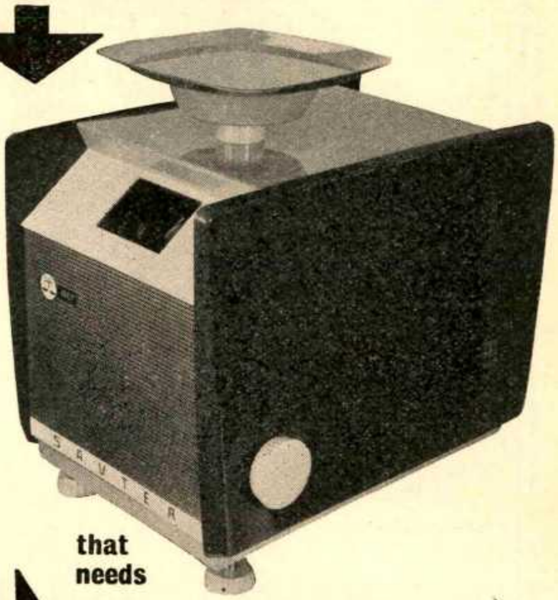
The Precision Balance



that needs

NO LEVELLING

with these outstanding features, too

- *TOP-MOUNTED PAN*
- *BACK AND FRONT READING SCALES*
- *NEAR-INSTANTANEOUS MAGNETIC DAMPING*
- *SUBSTITUTION PRINCIPLE*

Here's a superbly-designed substitution precision balance that offers really worthwhile new features—a **built-in levelling device** making critical levelling unnecessary; a **clear, illuminated scale both back and front,** making checking easy; **almost-instantaneous magnetic damping;** large, conveniently-mounted, **interchangeable top pan.** The Sauter TOP-PAN **is** what it **looks**—an intelligently-designed finely-engineered solution to an old problem. The TOP-PAN is available with capacities of 1 kg (0.1 g divisions), 2 kg and 4 kg (both with 1 g divisions). Models are also available with a special tare facility, but without the levelling device.

Write to-day for full details and a demonstration on your own premises.

SHANDON

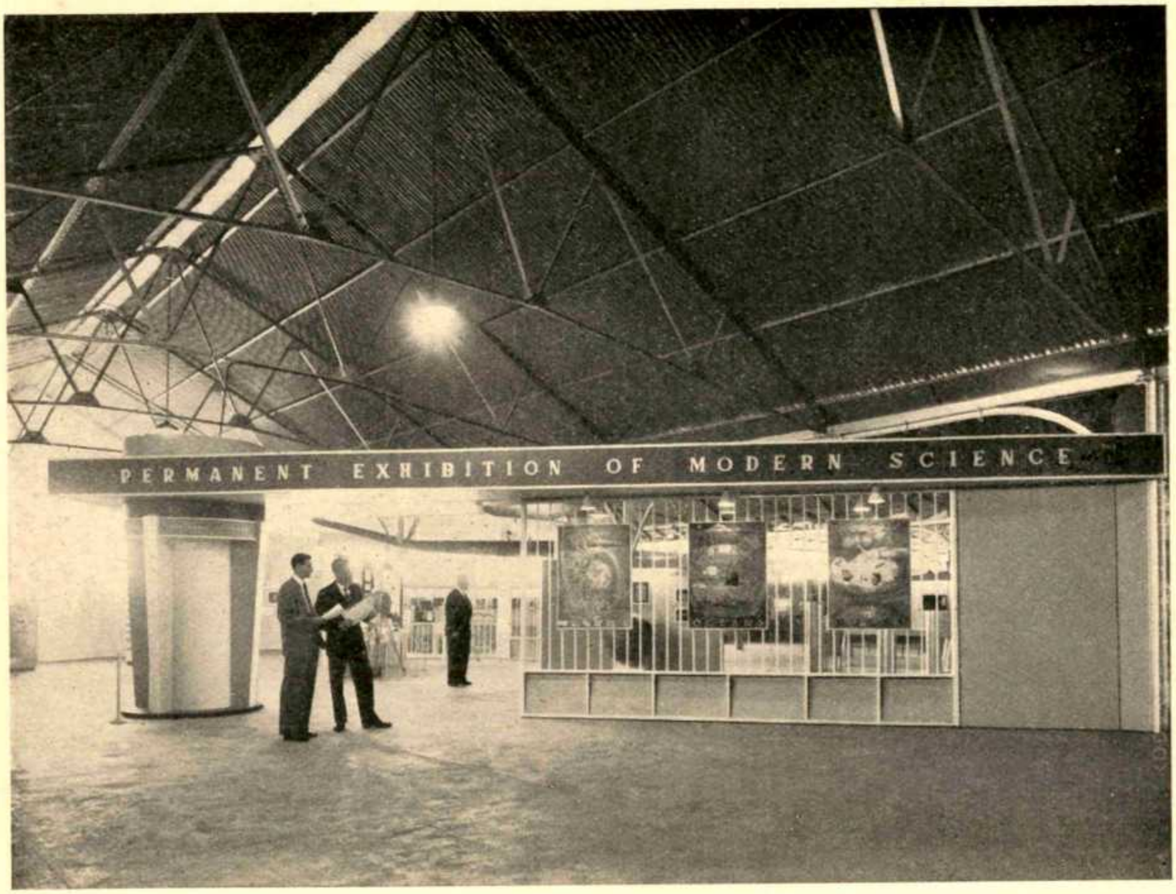

Fig. 1. Entrance to the Exhibition of Modern Science, Pretoria. The three posters seen in the foreground form part of a display symbolizing the main theme of the International Geophysical Year: space, Sun and Earth, weather and climate, oceans and poles

The inhabitants of the capital of South Africa have taken the initiative, and quite rightly so, for nowhere on the continent of Africa is scientific research and activity more concentrated than in and around Pretoria. Here are situated the headquarters of the Council for Scientific and Industrial Research with its two national research laboratories, seven national research institutes, the South African Bureau of Standards and associated activities; the headquarters of the Department of Agriculture, with its numerous research divisions including chemical services (soil fertility), botany, plant pathology, horticulture, dairying and the famous Veterinary Research Institute at Onderstepoort; the Department of Forestry, the Geological Survey and Trigonometrical Survey; the Weather Bureau and the Radcliffe Observatory; the National Zoological Gardens, National Botanic Gardens and the Transvaal Museum; the Fuel Research Institute and the developing research laboratories of the South African Iron and Steel Industrial Corporation (Iscor); the University of Pretoria, with its rapidly developing faculties of medicine and engineering, in addition to the faculty of science; and the University of South Africa, Pretoria. Here, too, are the headquarters of the various agricultural marketing boards.

As these scientists seldom meet except in their own specialized groups, it has created an opportunity for scientists from different fields of specialization to meet together and even more so to work together on matters of common interest. Furthermore, scientific organizations are obliged to participate from time to time in shows and exhibitions which involve a great deal of time, effort and expense; these exhibits are usually on display for relatively short periods, after which they have to be broken down. The result is that all the effort and expense are virtually lost.

It was against this background that on February 5, 1960, Mr. Kingwill, head of the Information and Special Services Department of the Council for Scientific and Industrial Research, proposed the establishment of a Permanent Exhibition of Modern Science to a meeting of Pretoria members of the South African Association for the Advancement of Science. The proposal was accepted and an organizing committee appointed. The committee found immediate support from the Pretoria City Council, the Northern Transvaal Chamber of Industries, the Transvaal Museum, the Council for Scientific and Industrial Research and South African Iron and Steel Industrial Corporation. It was decided to launch the Permanent Exhibition of Modern Science in conjunction with the Pretoria Industrial Show, in one of the halls with an area of 30,000 sq. ft., which the Pretoria City Council agreed to make available for an indefinite period.

The success of the exhibition depended entirely on the support of the main research organizations in Pretoria in order to be able to present a reasonably complete picture of research in science and engineering in relation to the development of the material and human resources of South Africa. Despite the short

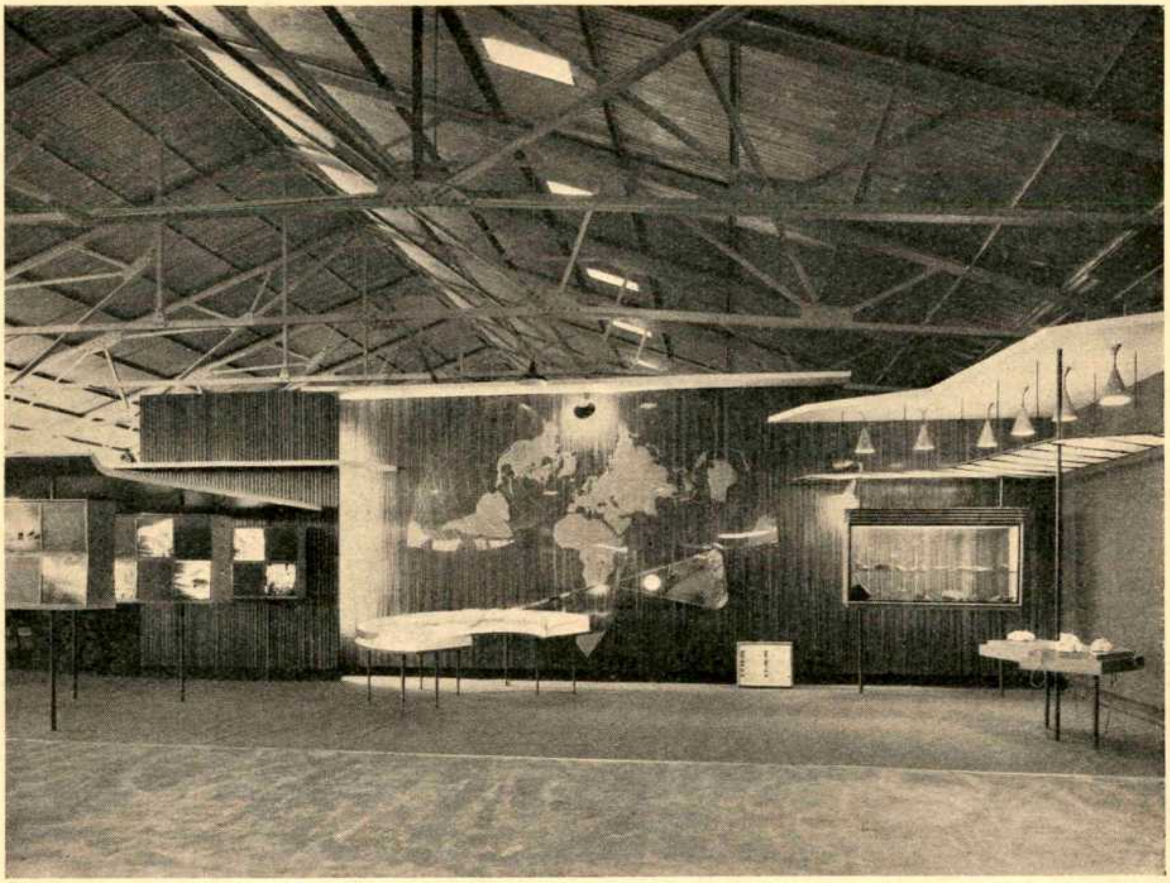

Fig. 2. An exhibit first shown at the Atoms for Peace Conference in Geneva, illustrating the occurrence and mining of uranium in South Africa

notice this support was forthcoming. In addition, exhibits on sugar production were provided by the South African Sugar Association, paper production by the South African Pulp and Paper Industries, on power generation by the Electricity Supply Commission for South Africa, English Electric and John Thompson, Ltd., petroleum by the Shell Co. of South Africa, Ltd., aviation by British Overseas Airways Corporation, gas turbines by the South African Air Force, and the recovery and uses of diamonds by the Diamond Research Laboratory. Major contributions were received from the Information Offices of the United Kingdom and the United States—the former on radioactivity and nuclear power, the latter on space research.

As a result of this wonderful co-operation and support, it was possible to stage a very comprehensive exhibition of modern science in an unbelievably short time. The exhibits have been so arranged that they lead the visitor from research on outer space and its relationship to the measurement of the Earth, to the measurement of the ionosphere, on which we are dependent for long-distance radio communication, to meteorological observations and weather forecasting; and from there to research on hail, air-pollution and radioactive fall-out. Descending to Earth the structure and interrelationships of rock formations are explained. These are followed by exhibits illustrating the mining, recovery, preparation, transformation and utilization of coal in South Africa. From here the exhibition leads off in three directions: the use of coal in the generation of electric power; the occurrence of uranium in association with gold in South Africa, the processing and use of uranium in the generation of electric power, radioisotopes and the cultivation of the surface of the Earth, that is, agriculture.

The main aspects of agricultural research, such as soil and vegetation, crops and pastures and animal husbandry are demonstrated in comprehensive displays. In the exhibit on forestry the following aspects are dealt with in detail: afforestation, genetics and tree breeding, plantation operations, saw milling, seasoning, grading, uses and wood products. With this exhibit is associated an exhibit on the production of pulp and paper.

The theme then switches to the basic sciences of chemistry and physics. Exhibits dealing with X-ray crystallography, spectrochemical analysis and the three techniques of chemical separation, chromatography, ion exchange and distillation, illustrate that the separation and identification of substances is an important aspect of science. These displays are followed by an exhibit on the history, meaning, purpose and application of standardization. Parallel to them are exhibits on engineering: gas turbines and aviation, stress analysis, slag cement, steel production and the exploration, recovery, transportation and uses of petroleum.

This leads to research on public services: road construction and maintenance, traffic engineering and road safety; the treatment and purification of water supplies and sewage effluents; vitamins, trace-elements and nutrition; Bantu housing and, finally, aptitudes and abilities of the people of South Africa and their adjustment to changing conditions.

The present housing of the exhibition in the Pretoria Show grounds is a temporary arrangement, and eventually it is intended to provide permanent accommodation which will be more conveniently situated. A film auditorium is included in the exhibition hall, and on Wednesday evenings a programme of lectures and films is arranged to amplify the exhibits in the hall and other items of general scientific interest.

The establishment of the Permanent Exhibition of Modern Science has been made possible through the voluntary efforts of members of the organizing committee and the support and co-operation of numerous sponsors. It is a long-term project, and success will depend on continued support and sponsorship of industrial, commercial and public undertakings; on the active participation in its activities by scientists working in these organizations; on the interest and participation of school teachers and scholars; and on the Association for the Advancement of Knowledge and Culture.

OBITUARIES

Prof. Camille Guérin

PROF. CAMILLE GUÉRIN died on June 9 in Paris in the hospital of the Pasteur Institute after a long illness.

Probably not all who are aware of, or are responsible for organizing, vaccination with BCG, finally but only very recently accepted in Britain as safe and effective and having an important ancillary part to play in the control of tuberculosis in man, recognize that the initials perpetuate so eloquently the close and fruitful collaboration of two of the most illustrious of Pasteur's disciples which, more than forty years ago, resulted in the development of this antituberculosis vaccine—Bacille Calmette-Guérin.

Guérin was born in Poitiers in La Vienne on December 22, 1872. He pursued his veterinary studies in the Ecole d'Alfort near Paris. It was fortunate that Nocard, one of the professors at this school, realizing his interest in research in the bacteriological field, initiated Guérin's technical training and encouraged his vocation. Nocard was an able master, for he was associated with Pasteur in the early studies on rabies in the rue d'Ulm and later, in addition to continuing his teaching at Alfort, he brought his clinical science and experience in experiments on animals to a collaboration with his friend Roux at the Pasteur Institute in studies on tuberculin, mallein and on the development and improvement of bacteriological techniques, just as Guérin did later to his collaboration with Calmette. It was Nocard who brought Calmette and Guérin together.

In 1896, the year following Pasteur's death, Calmette was appointed director of the newly founded Pasteur Institute in Lille on his return from a mission to Saigon, starting in 1891, to establish a centre for smallpox vaccination and for the diagnosis of and vaccination against rabies with the Pasteur vaccine. This latter became one of the three Pasteur Institutes in the great French colony of Indo-China.

In 1897 Guérin was appointed assistant to Calmette in Lille. Their collaboration lasted for thirty-six years and was only terminated by Calmette's death in 1933.

As Guérin once waggishly commented, he could not be accused of having tackled too many problems without devoting sufficient time to any one of them. Only two were the subjects of his researches, vaccinia and tuberculosis. Experiments on Jenner's vaccine were indeed the first subject of his researches, and the regeneration of the virus by passage on the shaved skins of rabbits led to an original method of titrating the virus which was later adopted in 1927 by the League of Nations for the standardization of the vaccine for smallpox.

However, it was to the experimental study of the bacillary infection and the immunity against tuberculosis that in collaboration with Calmette he consecrated the major part of his long scientific career, extending over forty-six years. They had come to the conclusion that only a living vaccine would be likely to prove efficacious, and their long, patient efforts from 1908 over a period of thirteen years, during which a bovine strain of tuberculosis was passaged 230 times in a medium to which they had added bile which they had found in early work had an attenuating effect on the bacilli, finally led to a culture which proved to be non-infective for guinea pigs and cattle while retaining immunizing properties for these species. Investigations were made on the stability of this attenuated culture in respect of lack of tendency to reversion of pathogenicity when subcultured in media without bile or evidence of similar reversion in vaccinated animals. At this stage consideration was given to the possibility that the vaccine would be safe and effective for the immunization of man. The first vaccinations of children were carried out by Weill-Hallé in 1921 with successful results. BCG vaccination became increasingly popular so that in 1928 the number of vaccinated children in France increased to more than 100,000. During this period the activities of the Lille Institute had been interrupted by the 1914–18 War. In 1919 Calmette went to the Pasteur Institute in Paris, where Guérin soon joined him to continue the work. Their culture is the parent of all the cultures used for BCG vaccination, and the number of persons vaccinated with BCG throughout the world is now estimated to be about 200 million. There is no evidence of reversion to virulence in the body of vaccinated persons. Moreover, following trials organized by the Medical Research Council (Rep. 1956, 1958 and 1959), which indicated safety, substantial protection for at least 6½ years and satisfactory conversion-rates to tuberculin sensitivity following vaccination with liquid or freeze-dried BCG, it has at long last come to be recommended in Britain for the vaccination of infants born to tubercular parents, children of 13–14, doctors, nurses and medical students coming in contact with tubercular patients and those who have been in contact with cases of open tuberculosis, provided that all these categories show negative results in tuberculin tests before vaccination. The important part that BCG can play in economically developed countries, as it is pointed out, must be considered as ancillary to all the instruments available for the control of tuberculosis. These have been listed in a recent review by an eminent professor and expert in tuberculosis, J. W. Crofton, as BCG and the general improvement in the standard of living to raise community resistance, miniature radiography, chemotherapy, appropriate isolation, improved ventilation and the reduction of overcrowding in home, work, play and transport.

Reference is also made to control of bovine tuberculosis; with regard to this it is appropriate to mention the recent announcement by the Ministry of Agriculture that October 1, 1960, marked the end of a concentrated effort to reduce the incidence of bovine tuberculosis in Britain to a degree that it is no longer a national problem in that it has been virtually eradicated by attestation of the herds of the whole country. It is stressed that the present position with regard to human tuberculosis does not justify complacency. However, it is considered that a stage has been reached when it is possible to see how the main weapons against tuberculosis can be applied, and that provided there is enthusiasm and public backing to the end, there is a prospect of foreseeing the elimination of tuberculosis in the not too distant future. The problem in the undeveloped countries is more difficult. It is commented that BCG has an important part to play in economically developed countries, and it might be even more useful in the others provided that the efficacy and appropriate use of the vaccine is kept under constant review in the laboratory and in the field.

In this connexion it is interesting that what is considered as one of the most convincing studies of the protective power of BCG vaccination was first reported by Aronson in 1948. North American Indian children and young adults who did not react to tuberculin were divided into groups of 1,550 vaccinated with BCG and 1,457 unvaccinated. There was segregation of the first group for two months after vaccination. Tuberculin testing and radiographic examination was carried out each year for seven years and at the end of this period 4–5 times more unvaccinated had developed tuberculosis than the vaccinated and the mortality-rate from tuberculosis was seven times higher in the unvaccinated. It is interesting to note, in view of the early demonstration by Calmette and Guérin of the immunizing value of BCG in cattle, that it is now considered that control of tuberculosis should, whenever possible, be by an eradication scheme based on attestation of herds by tuberculin testing. Since BCG vaccinates are sensitized to tuberculin, diagnostic procedures are difficult and thus BCG can play no part in such a scheme. Nevertheless, although the BCG vaccine has become established as safe and effective, it had a very stormy history and one of the roughest passages of any vaccine before final acceptance. Undoubtedly, one of the major setbacks was the unfortunate incident in 1930 in Lubeck in Germany when 78 out of 251 infants believed to have been vaccinated with BCG, but who as was later established by official inquiry had been inoculated in error with fully virulent human culture of the tuberculosis bacillus, died. Until the result of the official inquiry had confirmed that BCG was not responsible, Calmette and Guérin suffered adverse criticism and vituperation from all quarters, including that from those who had warned that reversion to virulence was possible and here was the proof. Although BCG was exonerated, the incident had unfortunate repercussions, and it was a very long time before confidence in the safety and efficiency of the vaccine was established. Calmette especially was greatly shaken by the incident. He did not have the resilence of Pasteur in dealing with his detractors. The worry, strain and the vilification by the critics together were too much for him. He died in 1933, a disappointed man broken in spirit and health.

Guérin continued the fight against tuberculosis as chief of the BCG service in the Pasteur Institute for another ten years, consolidating the victory, opposing the doubts and critics with his lucid, well-considered judgments. Even after his retirement, he gave encouragement and advice to those who took over from him. Guérin was a member and president or vice-president of many learned societies and, in addition to receiving many foreign decorations, his contribution to the control of tuberculosis was recognized with gratitude in 1952 by the award of the Grande Médaille de Vermeil de la Ville de Paris, in 1955 by a prize of one million francs by the Academy of Sciences and appointment as Grand Officier de la Légion d'Honneur in 1958.

Those who knew Guérin recognized his charming modesty and great affability, and what gave him the greatest satisfaction was presiding at the First International Congress of BCG in 1948 and the opportunity of surviving long enough to witness the ultimate success of BCG, the universal recognition of the safety and efficacy of the vaccine which he and Calmette had struggled to develop nearly half a century ago.

IAN A. GALLOWAY

Prof. R. M. Gordon, O.B.E.

RUPERT MONTGOMERY GORDON, professor emeritus of parasitology and entomology in the School of Tropical Medicine, University of Liverpool, died on July 26, 1961, aged sixty-seven. During his youth he lived in Phoenix Park, Dublin, and there he developed early an interest in biology. He graduated in medicine in Trinity College, Dublin, in 1916, and, joining the Royal Army Medical Corps, he spent the war years in the Middle East. He was demobilized in 1919 and joined the staff of the Liverpool School of Tropical Medicine. He was soon sent to work for some two years in the School's laboratory at Manaos in Brazil, and on his return he became house physician and clinical pathologist to the Tropical Ward in Liverpool. In 1924 he was transferred to the Sir Alfred Lewis Jones Research Laboratory in Sierra Leone, where he became director in 1929 and professor of tropical diseases of Africa. In 1937 he returned to Liverpool to the chair of entomology, and in 1941 he became the first occupant of the Dutton and Walter Myers chair of entomology and parasitology.

He was president of the Royal Society of Tropical Medicine and Hygiene during 1955–57, and he was awarded the Chalmers Memorial Gold Medal in 1937. On his retirement he received the Mary Kingsley Medal of the Liverpool School of Tropical Medicine. He was an active member of many scientific committees and an editor of the *Annals of Tropical Medicine and Parasitology* for 28 years. In collaboration with Dr. M. M. J. Lavoipierre he completed a text-book on medical entomology shortly before his death.

Prof. Gordon was author of more than one hundred scientific papers which covered a wide range of subjects. In addition to many minor studies he made major contributions to medical parasitology in connexion with the epidemiology of malaria; the vectors of schistosomiasis and the development of the worms in the final host; metazoan immunity; the reaction of the human host to the bites of insects; the epidemiology of filariasis, especially loaiasis; and the deposition and development of trypanosomes deposited in the mammalian host by tsetse flies. One of his most notable achievements was his investigation of the behaviour of the mouthparts of blood-sucking arthropods during the act of feeding. He and his colleagues devised a method by which the mouthparts could be photographed on cine colour film in the host's tissues while feeding, and several cine films were made.

As a man, Prof. Gordon earned the affection of his junior staff and colleagues. He was deeply loyal to the School and to his friends, and he took a personal interest in encouraging the development of his young research workers. He was a tireless worker, a very fine teacher and an amusing companion. His wide experience and broad vision enabled him to throw fresh light on any problem he investigated, and his stimulating approach and constructive criticism will be sadly missed by workers in the field of medical parasitology. T. H. DAVEY

NEWS and VIEWS

Fluid Mechanics at Glasgow :
Prof. T. R. F. Nonweiler

DR. TERENCE NONWEILER has been appointed to the Mechan chair of aeronautics and fluid mechanics at the University of Glasgow in succession to the late Prof. W. J. Duncan. For the past four years Dr. Nonweiler has been a senior lecturer in aeronautical engineering at the Queen's University of Belfast, having previously held the same office at the College of Aeronautics. For some years he has acted as consultant to the Admiralty. He is an Associate Fellow of the Royal Aeronautical Society and also of the Institute of Aero Space Sciences and a Fellow of the British Interplanetary Society. Dr. Nonweiler is well known for his many contributions to theoretical aerodynamics, to space technology and to the problem of the stability of submarines. In addition, he has been a moving spirit in the recent campaign for the achievement of man-powered flight.

The appointment of Dr. Nonweiler to a chair with responsibilities for the education of both aeronautical and mechanical engineers is particularly felicitous in that his interests and experience cover the whole range of fluid mechanics. Moreover, several fields in which he has long been interested are likely to become increasingly prominent in the immediate future.

Progress on the Advanced Gas-cooled Reactor at Windscale

THE 135-ft. diameter containment building which encloses the advanced gas-cooled reactor, now nearing completion at the Windscale Factory of the Atomic Energy Authority, Cumberland, was successfully tested over the August Bank Holiday week-end. The holiday period was chosen so as to cause minimum interference with other work on the site and with the Factory. Very satisfactory results were obtained from sub-atmospheric strength and leak tests. The pneumatic strength test at 12·5 lb./sq. in. (gauge) necessitated the diversion of traffic from the adjacent public road as a precautionary measure. The advanced gas-cooled reactor represents the next phase of development of the graphite-moderated gas-cooled reactor beyond the basic Calder Hall design adopted for the first round of British nuclear power stations now being built. The main objective of the reactor is to reduce the capital cost of reactor installation, and this will be done by raising the steam temperature and increasing thereby the amount of heat generated from a given size of reactor. Higher temperatures will be made possible by the use of uranium oxide fuel, which will be put into the reactor in stainless steel and beryllium 'cans'.

Industrial Water and Effluents Group

A NEW group of the Society of Chemical Industry, to be known as the Industrial Water and Effluents Group has been formed under the chairmanship of Dr. B. A. Southgate, director of the Water Pollution Research Laboratory of the Department of Scientific and Industrial Research. The new Group will be concerned with the broad subject of industrial water, from supply, through treatment and use, to ultimate disposal. Among the subjects which will receive special attention by the Group are: availability of water for the future needs of industry; quality requirements for water for industrial use; treatment of water for process, steam raising and cooling purposes; conservation and re-use of industrial water; methods of treatment and disposal of water-borne wastes; industrial location and development, as governed by water supply and waste water disposal facilities; effects of industrial effluents on natural waters. The first meeting of the Group will take place at the Royal Institution, Albemarle Street, London, W.1, on November 1. Applications for membership and further information can be obtained from the General Secretary, Society of Chemical Industry, 14 Belgrave Square, London, S.W.1.

Atomic Research and International Co-operation

A REPORT, *New Trends in Atomic Research and their International Significance*, prepared by Dr. L. Kowarski, scientific adviser to the European Nuclear Energy Agency, and submitted to the Agency's Steering Committee, surveys the scope for international action in nuclear research and the opportunities of co-operation and makes several suggestions for such action (Pp. 36. Paris: Organization for European Economic Co-operation, European Nuclear Energy Agency, 1961). These are to be examined by a meeting of experts from member and associated member countries which is expected to take place during October. Dr. Kowarski assumes that fundamental research in this field is likely to be carried out in a clearly autonomous division of a large centre or in a separate centre, and that the need for large-scale planning, especially in semi-applied research, will encourage international co-operation. He believes that, although international co-operation is compatible with secrecy regulations only under exceptional conditions, in normal times the temptation to secrecy can be kept within reasonable bounds and channels of information kept open. Of the opportunities for co-operation, he lists first studies on high-flux reactors, followed by the application of electronic computation to reactor technology. Reactor physics also offers considerable possibilities, particularly through the pooling of material resources, as does the conversion of fission-generated heat into electric power. Besides the advanced types of power reactors, research on materials and components, research on miscellaneous applications of nuclear energy whether in medical or biological research, the sterilizing irradiation of food or other utilization of by-products, and problems of the disposal of waste materials offer important opportunities. The concrete suggestions for co-operation made in this report are, first, the creation of an 'Advanced Proposals Committee', to scrutinize new trends and ideas in this field, together with study groups on the direct conversion of nuclear energy to electric power and on data processing. Authoritative discussions could also be initiated into possibilities of co-operation on fluid-fuel and heavy-water reactors, making full use of the potentialities which already exist at Oak Ridge, particularly in the molten-salts reactor.

The Frederick Soddy Trust

THE report of the Frederick Soddy Trust (dated September 1958. Pp. 16. (Hove, Sussex: The Frederick Soddy Trust, 9 The Drive)), gives some indication of the principles to be employed in selecting projects for support, and these are further emphasized by the list of rejected applications by August 1957 and the record of grants made up to September 1958 which are included in the report. One further application, a large-scale and ambitious project for studies in a Central American desert, was rejected because it required support on a much larger scale than the Trust was able to give. On the principles themselves, the report emphasizes that team work rather than individual work is to be supported; other things being equal, preference is to be given to original work leading to some published report, and the emphasis throughout must be on actual study and research in the field. Grants will normally only be made to persons reasonably qualified to carry out the work and, if possible, where the study is being carried out under competent and qualified leadership. Special value is to be attached to organized co-operation with local workers when field studies in a foreign country are undertaken. Some details are included of the programme of crofting field studies, 1957; the proposed study of Corby and the proposed survey of the parish of Ardington, Berkshire, by the University of Reading; and of a proposed expedition to the Pyrenees.

Australian Rock Art

ONCE again students of primitive native art have to thank Mr. F. D. McCarthy, who has recently published two articles in the *Records of the Australian Museum*. One deals with the rock-shelter paintings of the Conjola District in New South Wales (24, No. 13; March 9, 1959: "Cave Art of the Conjola District, New South Wales". Pp. 191–202+plate 22. Sydney: The Australian Museum); the other with certain rock engravings from the Sydney–Hawkesbury District (24, No. 14; March 9, 1959: "Rock Engravings of the Sydney–Hawkesbury District". Sydney: The Australian Museum). In both cases, conventionalized figures of animals and humans occur, as well as signs. Representations of footprints are especially noticeable among the engravings. The paintings occur in rock-shelters, the engravings on open rock surfaces. Among the illustrations given is a number of excellent photographic reproductions. So much has been done recently to render available to students this interesting native Australian art that one wonders when the various investigators, headed by Mr. McCarthy, will get together to produce a really worthy, well-illustrated volume on the subject. Museum articles and the like are all very well, but not everyone outside Australia can easily put their hands on them. It is time a more complete account appeared.

The Whaley Skull

AN interesting excavation was undertaken in Derbyshire by the late Leslie Armstrong, in company with the late Dr. Arthur Court, at the Whaley rock-shelter, not many miles from the more classic palæolithic sites at Creswell Crags. The work started so long ago as 1938, but the well-known skull was only unearthed in 1947. A number of archæological levels was identified, ranging from two Mousterian layers at the bottom to Aurignacian and proto-Solutrean levels above. Between the two series there was a sterile layer. The Whaley skull appeared to be a deliberate burial in the proto-Solutrean layer. Associated with it in the level were antler, bone and flint tools typical of the culture. The skull was buried with the base downwards and the frontal parts facing the wall of the shelter. Dr. Oakley has examined the chemical composition of the skull and the results obtained are in no way inconsistent with it being of Upper Palæolithic date, though from the point of view of the measurements of the skull itself it could almost equally be of a female of Neolithic date. In an article in *Man* of July 1961, D. R. Brothwell, of the Duckworth Laboratory of Physical Anthropology at Cambridge, describes the find in detail with comparative data from other sites. It seems likely that a proto-Solutrean family living in this rock-shelter carefully buried the skull of a woman who was fully adult, though the original suggestion that she was about fifty years of age now seems doubtful; but why she was carefully buried in the 'home' will never be known.

Natural Rubber Producers' Research Association

THE annual report of the Natural Rubber Producers' Research Association once more directs attention to the steady development of the natural rubber industry in the face of ever-growing competition from a variety of synthetics. Latest among these is the *cis*-1 : 4-polyisoprene rubber, which, for the first time, actually reproduces the essential structure of the natural rubber molecule, and which, with the closely allied *cis*-1 : 4-polybutadiene, is likely to prove a formidable challenge. This challenge is being met by concentration on improved efficiency in production and marketing, and by the continuous application of fundamental research. Among the more striking of the fundamental researches referred to is the discovery that the immediate precursor of the rubber hydrocarbon in the rubber plant is isopentenyl pyrophosphate. This substance has been shown to be converted rapidly into rubber in fresh latex. Another topic which is now becoming much clearer is the mechanism of rupture and fatigue failure. The well-known zig-zag type of tearing so characteristic of a good rubber is shown by photoelastic investigations to be a consequence of the classical stress-distribution pattern in the material ahead of a growing crack. The work on the chemistry of vulcanization, and the converse effect of degradation, has continued, and is enabling a consistent picture of the relation between the molecular structure and the physical properties of rubbers to be built up.

Railways in Rural Areas

PERHAPS inadvertently, the Newsletter of the Friends of the Lake District for June 1961 brings out clearly the dilemma which must confront railway authorities in determining their policy of supplying transport facilities in rural areas (Pp. 14. Ulverston, Lancashire: Friends of the Lake District. 1961). The association is keen that certain branch lines which provide passenger services during holiday periods should be preserved. To do this is quite uneconomical and involves considerable financial loss to British Railways. The dilemma is one which cannot be resolved by the interested parties alone and, if this desirable service is to be maintained, should be decided for all important branch lines by the Government as a means of preserving the nation's amenities.

Calouste Gulbenkian Foundation

THE chairman's report of the Calouste Gulbenkian Foundation, covering the period July 20, 1955—December 31, 1959 (Lisbon: Pp. xvii+201+17 plates), describes briefly the founder and the Foundation before outlining the investment and distribution policy which has been pursued. These have mainly comprised charitable activities and the arts in Portugal, with some work in education such as provision of scholarships (of which 122 were for study abroad, and 41 for study in Portugal; of these 45 were in the physical sciences, 80 in the medical and biological sciences and 34 in social sciences), and travelling libraries. Some limited assistance to scientific research in Portugal has been given through the provision of study, work and travel scholarships, grants to scientific institutions and for research projects and the establishment of a study centre for agricultural economics. A number of grants has been made for various purposes in the United Kingdom and elsewhere in the British Commonwealth. These include £10,000 to establish a Gulbenkian Fund at King's College, University of London; £22,000 for lecture rooms in the New Law Library, University of Oxford; £50,000 for three fellowships at Churchill College, Cambridge; £5,500 to the Pepys Library, Magdalene College, Cambridge, for preparation and publication of a catalogue; £12,000 to the Outward Bound Trust and £5,000 to the University College of Rhodesia and Nyasaland for an archaeological laboratory.

Theoretical and Applied Mechanics at the University of Roorkee

THE fifth annual congress on theoretical and applied mechanics was held during December 23–26, 1959, at the University of Roorkee, India, under the presidency of Dr. A. N. Khosla, the then vice-chancellor of the University. On the previous two days, December 21–22, a symposium on "Non-linear Physical Problems" was held at the University. The symposium was sponsored jointly by the Indian Society of Theoretical and Applied Mechanics and Unesco, and was presided over by Prof. F. K. G. Odqvist. Fifty-eight papers were presented at the congress and thirty papers at the symposium, and 132 delegates attended. Many of the papers have been published in scientific periodicals, but eighteen of the papers, including the presidential address by Dr. A. N. Khosla entitled "Shell Roof for 325 feet Auditorium Span at the University of Roorkee", presented to the congress, and fourteen to the symposium have been collected together and recently published as the *Proceedings of the Fifth Congress on Theoretical and Applied Mechanics; and the Symposium on Non-Linear Physical Problems* (Pp. xi+342. Kharagpur: Indian Society of Theoretical and Applied Mechanics, Indian Institute of Technology, 1960). The contribution by Prof. Odqvist is entitled "Engineering Theories of Creep", and an account is given of solutions of the problems of plasticity and creep as connected with bending of plates and stretching of membranes. Recent solutions obtained with Swedish digital and/or analogue computers are discussed.

Management of Pine Stands for Pulp-wood

TREES belonging to various species of *Pinus* are now widely used in afforestation operations because it is a feature of most species of that genus to be hardy pioneers able to adapt themselves to very exacting and exposed conditions. Because of the unfortunate habit of over-generalization and lack of discrimination—which has led in one case to the appearance of a text-book entitled *Conifers*, but which is solely concerned with certain species of pines—there has recently been an unwise tendency to accept certain revolutionary theories on the treatment of conifers, which might conceivably be applicable to some species of pine under certain special conditions, as worthy of general application in forestry. It was only a matter of time before the pendulum would swing back again, and it is perhaps quite significant and appropriate that this swing should receive an impulse from South Africa. Arising from the rediscovery that young or juvenile wood from trees 6–10 years old produces chemical pulp of inferior quality, J. J. Kotzé, writing on the management of pine stands for pulpwood, makes some very salutary comments (*Journal of the South African Forestry Association*, No. 35, 3; 1960). He says, among other things, that "diameter-size in the shortest possible time is of far less importance than quality and quantity. Closer initial espacement is thus indicated". By delaying thinning, lateral branch development is kept under much greater control than in the case of wider espacement and earlier thinning, while taper is reduced and the trees tend to become more cylindrical in form. There is also greater opportunity to select the best stems for further development, while the rotation can also be lengthened. These points, which have long been accepted by foresters, deserve to be emphatically re-stated. More care must be taken in drawing general conclusions for application in practice until adequate tests have been made over an adequate number of years—and in forestry that means very many years.

Mental Health Statistics

THE supplement to the Registrar General's statistical review on mental health for 1957 and 1958 continues the series dealing with statistics of patients admitted to and discharged from 'mental and mental deficiency hospitals' which began in 1949 (Pp. ix+102. London: H.M. Stationery Office, 1961. 7*s.* 6*d.* net). Previous supplements on mental health in this series have dealt with patients in designated hospitals who were under the provisions of either the Lunacy and Mental Treatment Acts or the Mental Deficiency Acts. By 1958 the modern attitude to mental sickness was finding expression in the de-designation of hospital beds for mental patients. In order to preserve the continuity of the statistics, an attempt has been made to maintain the same bed coverage in 1958 as in previous years, irrespective of whether the patients were statutory or informal. Consequently, the totals of admissions, departures and discharges, deaths and resident populations include all statutory patients for the years up to and including 1957, and for 1958 all statutory patients plus those informal patients about whom it was possible to obtain statistical information. Two trends are apparent in the departures and discharges: a general movement towards shorter durations of stay and an increase in the numbers of long-term patients leaving hospital.

Harwell Radiation Protection Course

THE fifth advanced course in "The Principles of Radiation Protection" will be held in the Harwell Reactor School during October 25, 1961–January 30, 1962. The course, which comprises lectures, practical work, demonstration and visits, is intended for graduates or persons of graduate standard either entering or already working in the field of radiological health and safety. The course will cover a wide field of fundamental background knowledge and will deal with principles rather than with particular techniques. Some of the lectures will be given by the staff of the school, but the majority will be delivered by experts from Harwell and other establishments of the U.K. Atomic Energy Authority. It is also hoped to have lectures from experts from the Medical Research Council, the Agricultural Research Council, the Central Electricity Generating Board, the Institute of Cancer Research, the Radiological Protection Service and the Ministry of Housing and Local Government. The fee for the course is £250, exclusive of accommodation, and application forms and further details can be obtained from the Manager, Reactor School, Atomic Energy Research Establishment, Harwell, Berkshire.

University News: Cambridge

THE following elections to posts in Churchill College have been announced. *Fellowship:* Dr. A. Hewish, of Gonville and Caius College, on appointment as College lecturer in physics. *Junior Research Fellowships:* J. A. Miller, of Selwyn College, for research in geophysics; R. M. Loynes, of Trinity College (Central Electricity Generating Board Fellowship) for research in mathematics. *Research Studentships:* N. W. Ashcroft, of the Victoria University of Wellington, New Zealand, in physics; S. J. Bernau (Canterbury, New Zealand), of St. John's College (Gulbenkian Studentship), in mathematics; G. R. G. Lewison, of Trinity Hall (Central Electricity Generating Board Studentship), in engineering; D. McCormack Smyth (Toronto), of Churchill College (Ford Studentship), in education; W. K. Stell, of Swathmore College, Penn. (Ford Studentship), in physiology. *Postgraduate Studentships:* S. Chatterjee, of University College of Science, Calcutta, for a course in statistics; E. A. Kohll, of the University of the Witwatersrand, for a course in chemical engineering.

Techne (Cambridge), Ltd.: 'Tempunit' Temperature Controller

THE 'Tempunit' temperature controller manufactured by Techne (Cambridge), Ltd., was erroneously priced at £15 in an advertisement in *Nature* of July 15. We understand from the manufacturers that the correct price is £25.

Announcements

SIR BERNARD LOVELL, director of the Nuffield Radio Astronomy Laboratories of the University of Manchester, has been chosen by the International Academy of Astronautics as the first winner of the Daniel and Florence Guggenheim International Astronautics Award. This Award, which carries with it a prize of one thousand dollars, is to be given each year to an individual who has made outstanding contributions to the progress of astronautics during the preceding five years.

MR. D. B. MACKAY, assistant chief officer for the past two years of the Official Seed Testing Station, National Institute of Agricultural Botany, has been appointed chief officer of the Station in succession to Dr. P. S. Wellington.

DR. DAVID M. GATES has been appointed editor of Section D, Radio Propagation, of the *Journal of Research* of the U.S. National Bureau of Standards. He succeeds Dr. James R. Wait, who has been editor of Radio Propagation for the past two years. Dr. Gates has been serving as assistant chief of the Upper Atmosphere and Space Physics Division in the Central Radio Propagation Laboratory at Boulder Laboratories. Previously he had been the scientific director of the London Branch of the U.S. Office of Naval Research.

THE third international conference on "Neurosecretion" will be held at the University of Bristol during September 8–13. Further information can be obtained from Prof. H. Heller, Department of Pharmacology, University of Bristol, Bristol 8.

THE Society for Water Treatment and Examination is holding its autumn meeting at Great Yarmouth during September 20–22. Further information can be obtained from the honorary secretary, A. W. H. McCanlis, 41 Carshalton Road, Sutton, Surrey.

THE Nutrition Society (Scottish Group) is holding a symposium at the large lecture hall, College of Agriculture, Edinburgh, on September 30. The subject of the symposium will be "Nutrition and Poultry". Further information can be obtained from the honorary secretary of the Scottish Group of the Nutrition Society, Dr. D. G. Armstrong, Hannah Dairy Research Institute, Ayr, Scotland.

A PROVINCIAL meeting of the Association of Applied Biologists will be held at the School of Agriculture, University College of North Wales, Bangor, during September 17–19. The programme will include material of interest to agricultural botanists, foresters (forest zoology and botany) and veterinary research workers. Further information can be obtained from J. Hobart, Department of Agriculture and Forest Zoology, School of Agriculture, Deiniol Road, Bangor.

RECENT SCIENTIFIC INQUIRIES IN PARLIAMENT

THE Parliamentary Secretary for Science, Mr. D. Freeth, dealt with a further 25 questions relating to science in the House of Commons on July 18, answers to which occupy 20 columns of the Official Report. Replying to a question about non-ferrous mineral resources in Cornwall, Mr. Freeth said that the results of a comprehensive study have been published in a Geological Survey memoir on the Metalliferous Mining Region of South-West England in 1956. Airborne geophysical surveys were undertaken in 1957, 1958 and 1959, and at present airborne magnetic surveys were being extended to the off-shore areas.

On international co-operation, Mr. Freeth said that high cost is an important but not the only factor in deciding whether an international project is desirable. The United Kingdom is participating in the European Organization for Nuclear Research, in the *Dragon* and *Halden* reactor experiments of the European Nuclear Energy Agency, in the Anglo-United States *Scout* satellite programme and a project for European space flights is under consideration.

Membership of the Machine Tool Industry Research Association incorporated in November 1960, includes 64 machine tool manufacturers representing about half the output of the industry, and 20 manufacturing firms in allied industries.

Repeated investigations by the Medical Research Council have shown no evidence of a higher incidence of lung cancer or respiratory disease among persons exposed to increased amounts of Diesel exhaust fumes. No figures are at present available to indicate the effect of Diesel smoke on road safety, but the Department of Scientific and Industrial Research is collaborating with the Minister of Transport in efforts to ensure the correct maintenance and operation of vehicles which will eliminate satisfactorily the nuisance from this source. Mr. Freeth also said that the Warren Spring Laboratory of the Department of Scientific and Industrial Research has examined methods for removing smoke from the exhausts of Diesel-propelled road-vehicles, but no device yet tested has proved satisfactory. The British Internal Combustion Engine Research Association is undertaking fundamental work on the combustion process in Diesel cylinders which it is hoped may lead to remedial measures. Mr. Freeth said it is a fact that correct setting of the injectors and their proper maintenance and operation provide a simple and effective remedy.

In answer to a series of questions on cancer, Mr. Freeth said that work on geographical variation in cancer incidence is already being supported by the Medical Research Council and no promising lead on cancer or similar diseases will be held up through lack of Government funds. The Medical Research Council's expenditure from public funds on cancer research was £327,000 in 1955–56 ; £400,000 in 1956–57 ; £486,000 in 1957–58 ; £499,000 in 1958–59 ; £583,000 in 1959–60 ; £650,000 in 1960–61 ; and would be about £783,000 in 1961–62. No reliable estimate can be made of expenditure on research relevant to cancer in the universities and medical schools in Britain from funds provided by the University Grants Committee, or in the National Health Service during the treatment of patients.

Other answers were as follows: The annual output of qualified scientists would be about 6,900 in the present academic year, compared with less than 5,000 in 1956, and the annual output of qualified technologists has grown from 6,200 to more than 9,600 in the same period. The Research Councils, for which the Minister for Science is responsible, are providing about £250,000 in the current year for expenditure on printing, publications and other forms of publicity. The Department of Scientific and Industrial Research at present operates 13 research grants with six different universities or colleges, and 6 further grants are contemplated. It is also intended to extend the use of scientific methods by the Geological Survey. A Committee of the Royal Society, at the request of the Advisory Council on Scientific Policy, is considering existing arrangements for supporting fundamental research in biology.

ATOMIC ENERGY RESEARCH AND DEVELOPMENT IN BRITAIN

THE seventh annual report of the Atomic Energy Authority covers the period April 1, 1960–March 31, 1961*, in which the Authority had in hand a special survey of its future requirements, both of man-power and finance, to ensure that its demands on Britain's resources do not exceed the minimum required for the efficient discharge of its responsibilities. This survey is additional to the periodic reviews made to ensure that the choice of reactor systems for major development and the priorities between them are firmly based. Although the review is still proceeding, its existence offers some re-assurance that developments on the part of the Central Electricity Generating Board will not lead to inappropriate duplication of effort. An increase in staff from 38,500 to 40,840 during the year is reported, industrial employees rising from 19,572 to 20,606.

On the civil side, the development of nuclear reactors to generate electricity on an economic basis remains the Authority's principal objective, and work for the nuclear power stations under construction, particularly the development and manufacture of magnox fuel elements, occupied a substantial part of the Authority's scientific and technical resources. Work on possible reactor systems for nuclear ship propulsion, production of radioisotopes (sales of which rose by 10 per cent to total nearly £21 million during the year) and development work on their applications, basic nuclear science, work on health and safety problems, and fulfilment of international obligations account for most of the Authority's remaining scientific work. Production of fissile material was up to programme, and unit cost was reduced by improvements in efficiency. The Calder and Chapelcross reactors, designed primarily to produce plutonium, are supplying more than 2,000 million units of electricity to the grid annually, and the stage has now been reached when the reactors are capable of generating more steam than can be used by the installed turbine capacity; turbo-alternators are being modified accordingly. In an experiment in a Calder reactor some of the standard fuel elements reached an exposure far in excess of their designed endurance. The production of a much more advanced type of fuel for the prototype advanced gas-cooled reactor at Windscale began during the year, and the main chemical extraction plant at Windscale successfully processed all the irradiated fuel from the eight Calder and Chapelcross reactors. A new separation plant is being constructed to process the irradiated fuel which will arise from the nuclear power stations operated by the electricity boards. The efficiency of the diffusion plant at Capenhurst was improved by about 4 per cent, and in addition to the highly enriched material taken from the top end of the plant, uranium hexafluoride was drawn off from the cascade at low enrichment to meet requirements for the prototype advanced gas-cooled reactor and for other research and development projects. In view of the great progress made since 1951, when work on the centrifuge method of isotope separation was abandoned, in fields such as vacuum engineering, the handling of uranium hexafluoride, and the design of gas bearings, a small development programme has been initiated to examine possible effects on this method of separating isotopes and the bearing of the new technologies on technical aspects of disarmament.

---

* United Kingdom Atomic Energy Authority. Seventh Annual Report for the period 1st April, 1960–31st March, 1961. Pp. viii + 80 + 4 plates. (London: H.M.S.O., 1961.) 5*s.* net.

Research and development undertaken in connexion with specific reactor systems are described in a separate chapter dealing with the reactor development programme. Research and development carried out with wider objectives, for example, the broad attack on scientific nuclear power problems, such as the effects of radiation on materials, the nuclear properties of materials and their effect on reactor performance, the chemical behaviour of materials in a reactor and heat-transfer problems, fundamental research in branches of science of particular importance to the Authority, and the research on isotopes or large sources of radiation, now centred on Wantage, are described in a further chapter. During the year, 517 technical reports have been published as well as 335 research articles by the Authority's staff in scientific periodicals, and lists of these publications are available on request. A further chapter of the report is devoted to controlled thermonuclear research.

Obviously it is only possible to select a few points for emphasis, and indeed even the Authority's report does not claim that its review of research and development is other than selective. A comparative economic study of various marine reactor designs made during the year indicated that, because of the comparatively small size of such reactors and the stringent safety precautions necessary if present reactor designs were installed in a ship, none of the designs at present in an advanced state of development is feasible, and the Authority is now considering the use of more advanced systems which are in a much earlier state of development. Much attention was paid to the reaction between graphite and irradiated carbon dioxide under the operating conditions of the Windscale advanced gas-cooled reactor, and the design for a large civil advanced gas-cooled reactor was carried forward in more detail. The Dounreay fast reactor is already fulfilling its purpose of developing the technology of fast reactors generally, and the next stage is intended to be a plant from which commercial fast reactors will be designed; work on this during the year was concerned mainly with reactor physics, engineering design study and the development of the fuel element, while work was started on the fabrication and irradiating-testing of possible fast reactor fuel elements. Much of the effort in support of the high-temperature gas-cooled reactor concept has been directed towards the 20 MW. (H) *Dragon* reactor experiment being built at Winfrith under the auspices of the Organization for European Economic Co-operation, but possible applications of this system to marine propulsion units and to large, land-based power stations are also being investigated. The way in which both gaseous and non-gaseous fission products diffuse out of graphite crystals and also through the pores of a polycrystalline mass of graphite is being studied. In preliminary work on the steam-generating heavy-water reactor system, a series of reactor physics experiments was performed in the *Dimple* and *Lido* research reactors.

In general research, investigations of the effect of irradiation on graphite, using the high-flux research reactors *Dido* and *Pluto*, suggested that changes produced by irradiation are essentially due to groups of interstitial atoms which congregate if the graphite is heated during or after radiation. The effect of neutron irradiation on the physical and mechanical properties of beryllium is being studied using electron microscope 'thin-film' techniques. In the increasing research on ceramic fuels a novel technique has been developed for the preparation of uranium carbide, with low open-pore space, by the 'reaction sintering' of uranium and carbon powders. Experiments on magnesium oxide have shown that its brittleness is due to the presence of surface cracks, less than one thousandth of an inch in length, which grow during deformation and lead to fracture. Investigations at Harwell directed towards studying the gas- and solid-flow patterns in fluidized material have shown that the roof of a bubble is robust, that a pocket of gas does not rise through a rain of solid particles, and that streams of gas adjacent to bubbles enter through the sides and bottom of the bubbles and rise inside them, suggesting that bubbles may help to promote gas mixing. A new method of automatic monitoring for beryllium has been developed in which a stream of the air to be examined is passed between platinum metal electrodes. A spark discharge between the electrodes excites the emission of light with wavelengths characteristic of any materials suspended in the air, and the light characteristic of beryllium can then be isolated and detected photoelectrically within a minute. A promising technique is being investigated in which wet steam is used as the cooling agent; if water is present as a film or spray, very high efficiencies for removal of heat can be obtained. In controlled thermonuclear research, work continued on the containment properties of the toroidal pinched discharge in *Zeta*, the ring-shaped apparatus in which deuterium gas is heated to high temperatures by an electric discharge. Investigation of plasma containment by magnetic fields oscillating at radio-frequencies have also been made, and in theoretical work attempts are being made to develop basic theoretical plasma physics, especially stability theory, to give predictions a secure foundation and to analyse individual experiments in detail, using available theory, to supplement and interpret the diagnostic measurements, suggest new experiments, and check the theory itself.

In written answers in the House of Commons on July 19, the Parliamentary Secretary for Science, Mr. D. Freeth, said that the volume of design work on reactor systems and other plant associated with the civil nuclear power programme carried out by industry on behalf of the Atomic Energy Authority is at the same level for 1961–62 as for 1960–61. The Authority received £2 million from the sale of fuel-elements in 1960–61, in addition to £6·5 million advance payments received in 1959–60, and expected to receive about £13 million from such sales in 1961–62. The three completed fuel canning lines at Springfields are fully employed, and all five lines are expected to be in production by May 1962, when the factory should be capable of meeting all demands now foreseen for natural uranium fuel-elements canned in magnox. It will be necessary in due course to plan new facilities for the fabrication of uranium oxide fuel elements if it is decided to include power stations using such elements in the nuclear power programme.

The Atomic Energy Authority now employs 350 professional staff on design studies and research and development for the prototype fast reactor, compared with 200 a year ago; but when full design and construction of a prototype commercial reactor can begin will depend on progress in developing a suitable fuel. Of the Authority's professional staff engaged on civil research and development, the proportions working on the main reactor systems in 1961 were: magnox reactors, 15; advanced gas-cooled reactors, 20; fast reactors, 14; high-temperature gas-cooled reactors, 8. In 1960 the corresponding figures were 20, 20, 9 and 8, respectively.

The Authority has in hand an intensive programme on the development of plutonium fuel elements for the prototype fast reactor. The fuels include mixed plutonium and uranium dioxides in a steel matrix and mixed plutonium and uranium carbides. The programme involves the preparation, irradiation testing and examination of specimen fuel materials, investigation of methods of making complete fuel elements and their testing under irradiation, and investigation of the behaviour of the fuel elements under conditions simulating those expected to be experienced in a power reactor. The number of professional staff engaged on the development of fast reactor fuels has approximately doubled since last year. It is not at present planned to run the Dounreay fast reactor completely on plutonium fuel, but shortage of plutonium is not holding up the development of fuel elements in the fast reactor. Ten engineers from the industrial consortia are attached to experimental reactor projects compared with 26 a year ago, and the Authority maintained a close association with the industrial consortia through a Nuclear Power Collaboration Committee and its supporting technical committees, including a joint committee which advises on the design and development of the Authority's experimental reactor projects and on advanced reactor systems. All information derived by the Authority on reactors is available to the industrial consortia through the Authority's reports, and the technology and progress have been discussed jointly under arrangements made by the Nuclear Power Collaboration Committee.

THE BRITISH GELATINE AND GLUE RESEARCH ASSOCIATION

THE twenty-first meeting of the Research Panel of the British Gelatine and Glue Research Association was held on May 17, under the chairmanship of Mr. S. G. Hudson (Richard Hodgson and Sons, Ltd.). The chair was taken in the afternoon by Mr. C. F. C. Simeons (British Gelatine Works, Ltd.).

Mr. W. G. Cobbett (British Gelatine and Glue Research Association) gave the first paper entitled, "Rupture Properties of Gelatine Gels". An apparatus has been built for the extension of dumb-bell shaped strips. The gels are cast from 10 per cent gelatine solutions in 'Perspex' moulds and are matured at 10° C. Extension is then performed at chosen constant rates, the gel strips being floated on mercury at 10° C. Rupture properties are more closely related to jelly strength (rigidity) than to the 40° C. viscosity of the gelatine solution. Thus gelatines with similar viscosities break at loads which follow the order of their jelly strengths while gelatines with similar jelly strengths are not greatly influenced in their breaking loads by differences in viscosity. The extension at rupture is greater for gelatines of higher jelly strength when the viscosities are equal, but is also higher for gelatines of higher viscosity where the jelly strengths are similar. The slope of the linear (lower) portion of the load-extension graph is directly related to the jelly strength as measured on the Bloom gelometer.

Discussion on the paper was opened by Prof. A. G. Ward, who had initiated the project in 1957. He recalled that the work was begun to provide information on the mechanical properties of gels in relation to food uses. The field was largely unexplored and it would be desirable to examine a series of fractions and a selection of total samples exhibiting extreme values in other physical properties. The lively discussion which followed showed that there was considerable interest in exploring the effects of additional variables on the extension properties of gelatine gels, for example, gel concentration and *p*H, chemical modification, including cross-linking, and dilution with additives such as water-soluble block polymers.

Dr. A. Courts presented his recent work on "Structural Re-orientation of Gelatine in Citrate". He has investigated the rise of viscosity with time which aqueous solutions of gelatines undergo over a period of days at moderate temperatures ($< 25°$ C.). The effect is enhanced several-fold in the presence of certain buffers, and most work has been done with approximately 0·3 per cent solutions in 0·15 *M* citrate at 20° C.; the rise is rapid during the first day, is slower but linear over the next 3–4 days and thereafter falls off. The rise is maximal near *p*H 7 and is unrelated in magnitude to the viscosity (log. viscosity number) of the sample and hence to its weight average molecular weight. It is dependent on the rigidity modulus of the gelatine and a quantitative relationship exists between the linear portion of the rate of viscosity increase and the rigidity. The increase in viscosity is explained in terms of partial reversion to a highly ordered state probably resembling that of the original collagen. This concept is supported by other properties of the matured solutions, for example, their ability to give fibres with precipitants and their resistance to complete digestion by trypsin. Dr. K. Little (Nuffield Orthopædic Centre, Oxford) showed some electron micrographs which she had obtained on the precipitated materials and which exhibited undoubted fibrous forms.

The afternoon paper, "Glueing in the Furniture Industry", was contributed by Mr. M. J. Merrick (Furniture Research Association). Attention was directed to the increasing mechanization of the modern furniture industry with the concomitant features of high production-rates and low labour content. Three main adhesives are in use, namely, animal glue, urea-formaldehyde and polyvinyl acetate. The more obvious differences between the properties of these, such as strength or resistance to water, have but a minor influence on the manufacturer's choice which is, instead, governed by the necessity for speed and reproducibility in the glueing of wood joints and veneers. Mr. Merrick then described the detailed operations involved in glueing in the furniture industry. A further point which emerged in the discussion was that synthetic glue manufacturers have built up an enviable technical service to ensure that the best use is made of the properties and behaviour of their products.

D. A. Sutton

RESEARCH BY SIXTH-FORM SCHOOLBOYS

By J. HEYWOOD

Department of Telecommunications and Electronics, Norwood Technical College, London, S.E.27

The editorial in *Nature* (**187**, 883; 1960) directed attention to the need for educational research and mentioned some specific topics. My work was cited as one of the examples in that editorial[1], and I have been concerned with several projects of this nature. The first has been concerned with project work for sixth formers, a second continuing the study previously mentioned[1] and a third into the opinions of technical college students on liberal studies. In this article the investigations made on project work will be discussed and some results presented.

This work has already been mentioned in *Nature*[2] since it has been carried out through the auspices of the Radio-Electronics Section of the British Astronomical Association. Four sixth formers have undertaken the same form of project and two of them have worked as a pair. The object was to provide a system of work which would have a liberalizing influence on the students' scientific studies and at the same time provide insight into the basic techniques of research inquiry. As an enticement the scheme aimed at providing some useful data for the Radio-Electronics Section.

Two of the students already possessed an interest in astronomy before the project was envisaged and were members of the Section. The other two were in attendance at the Salesian College, Battersea, and had no previous interest in astronomy or radio. Part of their project which is of considerable interest is at the moment in the press[3], and that of the third student will appear in the same publication[4].

Each project is in three parts, the first two parallel and the third being the item of use to the Section. The students were informed that their results should be written up in a form suitable for presentation as a 'letter' to *Nature*—there was of course no guarantee of publication anywhere but the concept of a letter in *Nature* gives the student an idea of how much has to be done to produce a small item.

An important feature of this work is the system of 'least instruction'. The students are encouraged to get on with the jobs themselves: at the same time they are equally encouraged to seek advice from their tutors but it is left to them to make the appointments. O'Neil and Borlengi[3] visited me at my home on four occasions during a three-month period and then submitted the article noted. This article was seen once previously and modified. In the case of Murdin[4], who already had an interest in radio astronomy and had worked with me previously, only two discussions were necessary. Murdin did, however, withdraw his article and make some additions before it was finally sent to press. These two articles summarize the scope and intentions of the first part of the project, while Sabbagh is concerned with the third part.

The fundamental units of radio astronomy provide an interesting introduction to the M.K.S. system and the relation between physical and radio units of brightness, brightness distribution and magnitude. A further comparison can be made with the unit of field strength as used in radio communications. In the first part of the project the student is given a number of references[5] which vary in level and told to investigate the problems of radio astronomy with particular reference to its units; he is asked to note how they differ from similar units used in optics and radio communications. His reactions to the various fields of observational radio astronomy are noted, and it is expected that a written account of this work in the form of the summary will be presented when complete. It is interesting to note that all the approaches to this same task have differed widely.

Normally the second part of the test is the construction of a simple piece of radio equipment with the view of its being used for observations. A typical project might be the construction of a sudden enhancement of atmospherics (associated with solar flares) recorder similar to that described by Ellison[6], or the construction of a simple radiometer[7] after Sander[8] or Osborne[9]. The third part would then consist of observing solar radiations or sudden enhancement of atmospherics (associated with solar flares) over a period of about two months. There is a number of possibilities open to simple investigation involving the analysis of such records.

At the time of writing all the students had completed the first part of the project. Sabbagh[10] had, however, undertaken a statistical analysis of some records made by Hyde and Castelvecchi[2] as a combined part two and three.

Two items arise from this research. First, it has been said that there is a large number of sixth formers with middle of the road Advanced level passes who would make good university students but who are nevertheless not able to obtain places. Secondly, it has also been said that there is far too much specialization in the sixth form arising from the need to cram. The shortage of university places accounts for the first and the shortage of time available to investigate candidates thoroughly undoubtedly assists this shortage. It would seem that projects such as those described would not only offset specialization, but also, if run on the lines of a second degree whereby an external oral examination was given on the candidates dissertation, provide the universities with a powerful means of selection. An alternative would be to offer a general paper on science subjects in which a candidate is required to write two fairly lengthy dissertations on any two of a variety of subjects announced during the two years preceding the examination. The former method seems to be the better since it offers the student an introduction not only to the wide aspects of scientific inquiry but to a knowledge of its tools.

UNIVERSITIES COUNCIL FOR ADULT EDUCATION

DURING 1959–60, as in 1958–59, there was a small increase in the total number of adult education courses over the figure for the previous year, from 4,741 to 5,051, and *prima facie* a striking increase in residential courses, from 351 to 575*. Apart from residential courses, the most notable increase was in the number of sessional courses. At 1,647 they reached a record maximum. This upward trend has been steady over the past few years, the average rate of increase since 1955–56 being about 5 per cent per annum. Alongside this increase the downward trend of tutorial classes has continued although the fall has been at a reduced rate, from 851 to 839, a reduction of only 12 compared with 46 and 53 in the two previous years. At Manchester, where the decline in the number of tutorial classes caused concern to the Joint Committee, a leaflet outlining the advantages of tutorial class study was printed and given to every Workers' Educational Association student who was not a member of a tutorial class. From Hull comes a reminder that "in general, tutorial courses offer more obviously and more fully, opportunities for the development of classes into strenuous seminar groups". Southampton, though regretting the reduction of this type of work, wonders whether the development of tutorial work has been pushed, in recent years, beyond reasonable limits. The report of King's College, University of Durham, contains this thought-provoking paragraph:

"Part of the answer to the decline in tutorial classes is that adult education is ceasing to be the 'late night' substitute it once was. There are fewer gaps in the educational system through which the potentially highly educable boy and girl can slip out of the main stream. While it is by no means infallible, and cannot be so long as the sill of the catchment area remains at the 'eleven plus', comparatively few pupils of good standard fail to make the grade if they try hard enough. The most grievous failure of the present system is that it so easily misses those who, at the vital age, are unaware of the need to make the effort and who lack parental pressure to encourage them to do so. Alongside the elimination of much of the earlier material from which adult students were made has gone some of the incentive to seek a higher education. The social scene of the early decades of the twentieth century has changed. The Welfare State needs a smaller quota of pioneers, dedicated to the attainment of social justice, and a much larger one of trained social workers, with qualifications, for the administration of its machinery. Moreover, progress in any occupation is now achieved through certificate, diploma or degree to a much greater extent than ever before, and the provision for those ends becomes steadily more extensive. So, the tutorial class, which in theory offered an opportunity for study for its own sake, but which in fact offered all kinds of other inducements, is less an attraction because it is less needed.

"The character of adult education is undergoing change no less than other factors of twentieth-century life and, although the tutorial class should continue to attract those who recognize its essential quality, universities may soon need to consider the introduction of incentives to it other than study 'for its own sake'."

One respect in which the character of adult education is undergoing change is the continued development of residential courses. Several departments comment on this as forming perhaps the most satisfactory side of their work. The residential course is a reflexion of changed social and economic conditions. "People are, on the whole, rather better off and at the same time they have many competing claims on their time. They prefer, wherever possible, to take their adult education in small and intensive doses, a limited commitment in a limited time, instead of spreading it over a long period of time, as in the past." Manchester is to be congratulated on the success which has deservedly crowned its persistent effort to demonstrate the importance of an extra-mural residential college.

Because of changes of classification, a strict comparison of the 1959–60 figures of subjects of study with those for previous years is not possible, but there seems not to have been any significant shift of interest. Indeed, the consistency of students' interests year after year, as revealed by the table of subjects studied, suggests either that there exists a peculiarly proper balance of subjects in extra-mural work and that it has been attained, or that students are notably conservative in their concerns, or that the pattern is largely shaped by the availability of tutors. The largest number of extra-mural classes in Wales was in religion, and clergy and ministers of religion formed the second highest category in the analysis of tutors.

---

* Universities Council for Adult Education. Report on the year 1959–1960. Pp. 28. (Bristol: W. E. Salt, Honorary Secretary and Treasurer, The University, 1961.)

The number of full-time tutors showed a slight increase over the previous years, and was almost the same as in 1956–57. Nevertheless, the increase in full-time tutors did not match the increase in courses, and consequently a larger number of part-time tutors was engaged, 3,838 compared with 3,512 in the previous year. This was a continuation of the trend noticeable during the past few years. The proportion of part-time tutors who are members of a university staff has at the same time declined slightly, but steadily, from 48 per cent in 1956–57 to 45 per cent in 1959–60.

Since the War, extra-mural work has expanded into fields such as archæology, music and the visual arts in which, though it is accepted that they are properly subjects of university study, a considerable proportion of the practitioners and exponents are to be found outside the universities. Moreover, dons become busier and more heavily committed. Belfast refers to the "growing reluctance of university teachers to make weekly journeys", Newcastle comments that "the prevailing apparent disinclination on the part of internal university lecturers to commit themselves to the longer course, especially if travelling is involved", and both Liverpool and London regret the transport difficulties which make it hard, or even impossible, for members of the internal university staff to travel to the remoter parts of their extra-mural areas. At a time when students have become more mobile, dons have become less so. This is a minor, less-prominent, feature of the mid-twentieth century social revolution; it creates new problems in maintaining the university complexion of extra-mural work.

Specialized courses which relate to a professional or vocational interest are now widespread. Manchester has a one-year training scheme for hospital welfare workers, a one-year public administration course for overseas Government servants, and a course on background to management for business executives which received the commendation of the Human Sciences Committee of the Department of Scientific and Industrial Research. At Liverpool there were several courses in the natural sciences at the postgraduate level, two of them, in applied mathematics and experimental botany, leading to a certificate. London has approved the introduction of a three-year course of study leading to a certificate in transport studies, and 1959–60 saw the beginning of the course for the diploma in the history of music. At Leeds, courses in such subjects as textiles, engineering, mining and fuel were arranged in association with internal departments of the University, and other courses were arranged for members of the staffs of the Home Office, the Prison Commission, the National Association for Mental Health, the National Coal Board, and the National Union of Mineworkers.

Courses of this kind are carrying universities into new fields where extra-mural departments are having to institute their own research. Leeds has received a grant from the Nuffield Provincial Hospitals Trust for work on the staffing of the hospital service, Liverpool appointed a research worker to study the impact of social change on adult education, and Oxford has embarked on a three-year scheme of research and experimental work in the field of trade union education.

These kinds of courses appeal rather to individual students than to pre-existing social groups, although it is always hoped that every class will grow into a cohesive social group. People move about much more often than they used to, and groups are less permanent. Continuity and progression of study needs to be thought of in terms of the individual more than of the group. The Leicester report, in its survey of the thirty years 1929–1959/60, contains a statement which would command at least partial acceptance generally:

> "There has also been a decided change in the ethos of the department's classes. Formerly, it was markedly social, now it is markedly individual. Classes and courses still grow into social unities, but this is now an incidental growth and it has not the educational significance which it once had. Rarely now do classes and courses become schools of citizenship as well as vehicles for teaching and learning in specific disciplines."

Another respect in which the change is noticeable is the educational background of students. The percentage of weekly wage-earners and of those with only an elementary or secondary modern education has fallen more than 40 to less than 10, and the percentage of professional workers and of those with a college or university education has risen from less than 10 to more than 40. Of the thousand students attending grant-aided extension classes at Leeds, more than 40 per cent had been to a university, teacher training college or technical college, and another 30 per cent had attended school at least until the age of sixteen. Almost half of them were under the age of thirty-six.

There are numerous examples of extra-mural classes undertaking field-work which has added to knowledge in botany, zoology, archæology and history. Under the tutelage of the Durham Extra-Mural Board, for example, a group of 15 students has investigated the site of a medieval village at West Whelpington, and their findings make a distinct contribution to the comparatively new venture of British archæology into the later Middle Ages.

MUSEUMS AND GALLERIES

THE recent report of the Standing Commission on Museums and Galleries stresses the responsibility of the British Government with regard to these institutions, and urges some immediate action*. Contrary to past practice, this sixth report covers only two years (1959 and 1960) instead of the usual quinquennial period. In emphasizing the need for more frequent reports, the Commission feels that this is a period of active rehabilitation in museums after a time of severe financial stringency. There is an increased public interest in them and higher standards are now expected.

---

* Standing Commission on Museums and Galleries. Sixth Report, 1959–1960. Pp. iv+64. (London: H.M.S.O., 1961.) 4s. net.

Although dealing chiefly with the national museums, the provincial institutions will welcome the recommendation of the Commission that the grant (now at £25,000) administered by the Victoria and Albert Museum for purchases should be increased in the next financial year.

With regard to buildings, there are at least thirteen projects which are to be regarded as of particular urgency. These include reconstruction of the war-damaged galleries at the British Museum, planning and construction of the final quarter of the Tate Gallery, erection of a new herbarium and library wing at Kew, construction of north-east and north-west wings of the Royal Scottish Museum, work on a west wing of the National Museum of Wales and extension of the Museum block of the Welsh Folk Museum.

The Commission urges museums to aim at a steady and rapid improvement in all their services and recommends that staff should be appointed to carry this out. It considers that these services should including cataloguing existing collections, the extension of late opening, provision of automatic guide lectures, and restaurants.

The Commission reiterates its recommendations in the previous report concerning estate duty, and income tax and surtax. It is pointed out that as it is not the policy of museums to finance themselves by entrance fees, apart from minor sources, only the taxpayer and private benefactors remain. It is thus felt that all bequests of money or money's worth should be exempted from aggregation and payment of estate duty, and that this should hold even if the donor dies within a year from the making of the gift. It is also considered that tax reliefs should be made in respect of gifts of objects or money, as the present British system of taxation offers no incentive to a benefactor to give to museums and art galleries during his life-time.

Those associated with provincial museums—and there are about 800 in the British Isles—will welcome the information that the Commission hopes to complete the survey and report, with recommendations, during the summer of 1962, possibly issuing an interim factual report some time in 1961. This will be awaited with great interest.

The report also includes an impressive survey of the individual institutions comprising the national museums in London, Edinburgh and Cardiff.

F. S. WALLIS

POPULATION MOVEMENTS AND MALARIA ERADICATION

IN the early months of 1960, a World Health Organization consultant, Mr. R. Mansell Prothero, visited the Sudan, Uganda, Kenya, Somaliland, Tanganyika, Zanzibar, Southern Rhodesia, Nigeria and Ghana to study the effect of population movements on malaria eradication programmes. In his report (*W.H.O. Chron.*, 15, No. 5–6; 1961) he observes that, although no method of measuring the extent of population instability has yet been devised, there can be no doubt of the high degree of such instability in Africa.

In all countries and territories visited by Prothero, there are considerable population movements from permanent villages to farms and back again. These usually involve the erection of temporary shelters for migrants on the farms. In the Sudan, for example, people move from one area to another during the cotton-picking season; in Nigeria, during the dry season, people go the valleys where there is still water to irrigate the land. Gambia receives many temporary immigrants from neighbouring countries for groundnut cultivation. Cultivation, planting and weeding coincide with the early months of the rainy season when malaria vectors are on the increase, and when temporary shelters provide suitable resting places for them.

Although the harvesting of such products as groundnuts, cocoa, and cotton attracts a considerable amount of labour, in many parts of Africa it occurs after the peak of malaria transmission. The same cannot be said of movements of labour to mining, industrial and commercial undertakings, since these occur all the year round.

Nomadic movements of pastoral tribes, which are on a larger scale than other types of population movement, occur only in certain parts of Africa, such as northern Sudan and Somalia. Fixed settlements are foreign to the way of life of these tribes; moreover, the environment in which they live compels many of them to wander with their flocks and herds. The only religious movement of any large size are those of the West African Mohammedans, north-east towards Mecca; these cause some convergance on the Sudan, but do not involve so many people as the internal migrations of the population of the country itself.

Apart from those connected with farming, most of these population movements occur without respect for international or political boundaries. Their effect on the stability of populations is considerable, and in fact, all malarial eradication pilot projects now in operation in Africa are hampered by them. It has so far proved impossible to start a malaria eradication programme for a whole country in Africa, because there is not one that contains population movements within its own boundaries. To keep migrants out of an area by using some kind of *cordon sanitaire* would not be practicable, because there are so many ways in which an African can get through natural or man-made boundaries if he wishes to do so. International co-operation in malaria eradication would only be a partial solution. These population movements are a fundamental part of the 'way of life' of the people. Some, such as pastoral nomadism, are traditional; others, such as migrant labour, are of more recent development. In either case, they cannot within a short time be stopped or easily controlled.

The situation must be accepted, and if it raises problems in malaria eradication, it will be necessary to find ways of adjusting to it. Malariologists in Africa must try to circumvent the problems that population movements raise for them in their work. But how, for example, is it possible to deal with the nomad pastoralist whose movements do not appear to follow any fixed plan, and whose huts, being mostly composed of grass and leaves, are not susceptible to effective insecticide treatment ? It is clear that there is no generally applicable solution to problems of this kind, and each of them must be considered individually on the same level as the malariological and entomological investigations that are now regarded as an essential part of malaria eradication programmes. Population distribution, settlement patterns, types of housing, farming practices, communications, water supplies and other relevant factors vary so much from one area to another that generalization is impossible. Geographical reconnaissance, as it now exists in eradication programmes, does not cover every aspect of population movement. Where necessary, it will have to be expanded to collect much wider information on the factors described, in order to understand the whole complex of physical environment, malaria parasites, vectors and people. It may then be possible to evolve the correct technique applicable to each individual local situation. The inclusion of professional geographers in some malaria teams for full-time work at the outset of a programme would be valuable; when they had collected the required information, it would not be necessary to retain their services, since the geographical data could afterwards be kept up-to-date by a specially trained sanitarian. There is also a need for detailed individual study of every migration problem arising in the course of malaria eradication in tropical Africa.

POLLUTION FROM REFUSE TIPS

TWO problems associated with modern living conditions are the disposal of house refuse and the reclamation of land from which chalk, gravel or other material has been removed. The possibility of solving these two problems at one blow by tipping the refuse into worked-out pits is attractive, provided that this can be done safely and without nuisance.

One of the dangers of this procedure, which is widely practised, is that water supplies may be contaminated by drainage from the refuse. To study this problem the Minister of Housing and Local Government, in 1953, appointed a technical committee to supervise experiments on the tipping of refuse, with special reference to the pollution of underground water. These experiments were carried out in the Laboratory of the Government Chemist, and the report on the results has recently been published, together with the conclusions and recommendations of the Committee*.

Two series of experiments were made: one on refuse tipped dry and the other on refuse tipped into water. The volume and composition of the liquid draining from the pits were determined, and the purification effected by passing this liquid through sand and gravel was studied.

The Committee points out that the matter is complex, and is careful to avoid over-simplified conclusions in its report. It appears, however, that the results of the experiments are reasonably encouraging and that, provided certain precautions are taken, the practice of tipping refuse may safely be continued and even extended. Although a highly polluting liquid is produced by percolation of rainwater through refuse, the amount of organic pollution falls off relatively rapidly with time. In addition, when refuse is tipped dry, a considerable amount of rain has to fall on it before any drainage water is produced. Thus if the amount of rainfall reaching the refuse can be reduced by covering the material with an impermeable layer as soon as possible after tipping, the total load of pollution discharged from the pit will be decreased. This is one of the reasons why the Committee considers that, under comparable conditions, dry tipping is less likely than wet tipping to affect water supplies adversely. It does not, however, rule out the use of wet sites, for the experiments showed that considerable purification of the liquid can be effected by percolation of the water from the pit through the surrounding ground. One suggestion of the Committee is that refuse might be tipped first into a dry pit, where initial decomposition would occur, and that after about two years it should be transferred to a wet tip, leaving the first site to be used again.

It is not claimed that the experiments described were exhaustive, and several lines of investigation remain to be followed. NORA H. JOHNSON

TOXICOLOGY OF *PENICILLIUM ISLANDICUM*

TOXICOLOGICAL research into the methanol extract of the fungus *P. islandicum* has been carried out since the spring of 1954, with collaboration in the fields of mycology, chemistry and medicine. In five biological testings, methanol extract prepared from the fungus mat of *Ub*, *Uc* or *Ea* strains was administered in the form of oil solution or water suspension to 150 mice and 10 rats, orally or subcutaneously, to observe pathological changes; in chemical testings, chemical fractionations of the methanol extract were carried out.

Biological data observed a few days after a single or several doses of the methanol extract had been administered have been summarized by K. Uraguchi, T. Tatsuno, M. Tsukioka, Y. Sakai, F. Sakai, Y. Kobayahi, M. Saito, M. Enomoto and M. Miyake of the Departments of Pharmacology and Pathology, Faculty of Medicine, University of Tokyo, Bunkyo-ku, Tokyo, Japan (*Jap. J. Exp. Med.*, 31, No. 1; 1961), as follows: Acute symptoms of poisoning are developed in mice and rats, but their life-time is prolonged with reduced doses. Poison damages show that abnormal function of the liver is detectable by the bromsulphthalein retention test, and autopsy shows, in most of the liver, centrolobular necrosis, fatty metamorphosis of liver cells and interconnexion between the necrotic areas with subsequent collapse; in part of the liver there is vacuolation of liver cells on peripheral parts of the lobules and hæmorrhage among liver cell trabeculæ.

From these results the investigators came to the conclusion that the extract must contain certain toxic agents injurious to the liver and acutely fatal to animals.

Before and after the twenty-fourth hour the symptoms differ from each other in a marked fashion. Pathological changes observed in the liver are of two kinds. It would appear that the biological response to the methanol extract must be a manifestation of two actions essentially different in properties but each injurious to the liver. Convincing evidence of this is obtained from the data concerning the solvents used for the methanol extract; rapid action seems to be detectable when the extract is suspended in water while delayed action is detectable when this extract is dissolved in oil.

With regard to the toxic metabolites of *P. islandicum*, the investigators concluded that, in the methanol extract of the fungus mat, two liver-injurious components co-exist which act fatally within a short time; one is a hydrophilic compound relatively rapid in action and the other a lipophilic compound which is much slower.

Chemical fractionation of the constituents in the methanol extract of the fungus mat indicated that lipophilic fractions, sterols and several pigments of the polyoxyanthraquinone group are obtained; among the latter is found a yellow pigment 'luteoskyrin', which has been unknown hitherto.

ICSU REVIEW

THE *ICSU Review* was initiated in 1958 as a new enterprise of the International Council of Scientific Unions, with the strong interest of the past president of Union, Dr. Lloyd Berkner. The intention was to have a publication especially devoted to the affairs of the Council with its thirteen federated scientific unions and its special committees. The *Review* would bring the progress now being made in the co-operation of working scientists from all over the world to the notice of specialists and a wider public which is not well informed on these activities. The new *Review* was edited by Sir Harold Spencer Jones.

After the death of Sir Harold, the position of the *Review* was considered and certain changes were thought to be desirable. The scope of the *Review* could be expanded so that it could cover even more effectively the full activities of the Union's constituent organizations. This objective could be reached only if the *ICSU Review* presents theories, projects or discoveries of world-wide importance, and is directed towards international science. It should bring members of the scientific community a knowledge of movements and trends in other sciences in a more comprehensive way than is done in the present scientific journals. To this end, the publication will in future include short articles from different branches of science, written in a style suitable for the non-specialist and the generally educated public. This will give a better presentation of the work of the scientific unions in its relation to the progress of knowledge and to world affairs; thus international co-operation will be presented in a living perspective.

The new issue (3, No. 1; 1961) is a first step towards realizing this goal and contains articles on *AGK*3—a co-operative programme in astronomy by F. P. Scott; international research programmes in oceanography by Dr. G. F. Humphrey; the world land use survey by Prof. L. Dudley Stamp; changing views on the Earth's crust by Prof. J. Tuzo Wilson; the mixed commission on the ionosphere by Prof. W. J. G. Beynon; biophysics by Prof. A. Engstrom; fluorine and African plants by Sir Rudolph Peters; a European project for a large observatory in the southern hemisphere by Dr. J. H. Oort; the international latitude service by C. A. Murray; and geophysical and space-tests of gravitational theories by Prof. R. H. Dicke. Dr. Donald Fraser has been appointed editor.

SYNTHESIS AND X-RAY ANALYSIS OF DIAMOND

By H. Ll. D. PUGH and J. LEES
Plasticity Division, National Engineering Laboratory, East Kilbride, Glasgow
AND
J. A. BLAND
Research Department, Plastics Division, Imperial Chemical Industries, Ltd., Welwyn Garden City, Hertfordshire

THE recent development of relatively simple ultra-high pressure equipment has stimulated research effort in this field. To the engineer the field is of importance because of its potential in producing a range of new materials, probably characterized by hardness and good refractory properties. A small team in the National Engineering Laboratory, East Kilbride, is investigating the synthesis of such new materials, and has constructed an ultra-high pressure apparatus capable of subjecting specimens to pressures of approximately 75,000 atm., and temperatures of approximately 2,000° K. In the proving of this apparatus, synthetic diamond crystals were produced. A detailed X-ray analysis was made of one of these, by the Plastics Division, Imperial Chemical Industries, Ltd.

The National Engineering Laboratory (U.K.) apparatus is based on the National Bureau of Standards (U.S.A.)[1] modification of the tetrahedral anvil apparatus[2]. In this apparatus the high-pressure cell

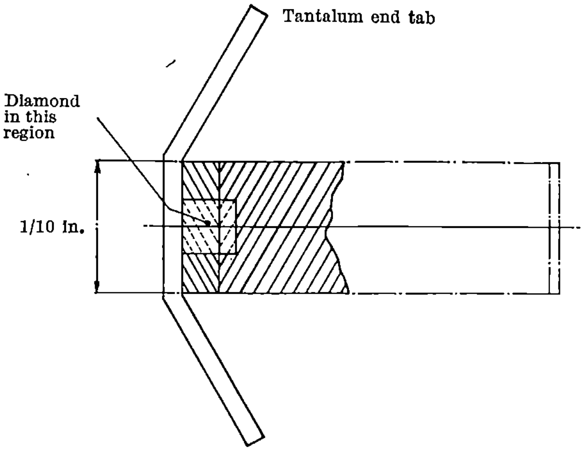

Fig. 1. Part of high-pressure cell containing nickel and graphite showing the region where diamond crystals were formed. Nickel, shading left down to right; graphite, vice versa

is a tetrahedron of pyrophyllite of ⅞ in. side, in the middle of which, extending between the centres of two opposite edges, is the test specimen 0·1 in. diam. × 0·3 in. long. The four faces of the tetrahedron are forced together by anvils acting on each face. Each anvil of tungsten carbide (6 per cent cobalt), force-fitted into *EN*26 binding rings, has a triangular face of ¾ in. side and is bevelled and shaped to fit with its neighbours so as to surround the tetrahedron completely except for small gaps. The excess pyrophyllite is initially extruded into these gaps, where it forms an efficient compressible seal allowing the bulk to transmit the pressure to the specimen approximately hydrostatically. The three lower anvils butt accurately on to the inner conical surface of a steel ring so that their thrusts are provided by wedging reactions when the top anvil is pressed downward. Contact tabs[2] enable the specimen to be heated by a large current, either through the specimen or through a graphite or metal tube surrounding it.

The apparatus was calibrated for pressure measurement in terms of the known resistance transitions of such metals as bismuth at 25,400 atm., and thallium at 36,700 atm. All pressures given here are in terms of the Kennedy and La Mori[3] recalibration, which shows Bridgman's resistance-transition values to be up to 30 per cent high. Temperatures were estimated by relating the heating power to that required to melt metal specimens, for example, nickel, for which data at high pressures are available[4].

The diamonds were synthesized using the arrangement of graphite and nickel shown in Fig. 1. With a power dissipation of 500 W., the specimen was heated to approximately 2,000° K. at a pressure of about 60,000 atm. for 30 min., followed by a 10-min. cooling cycle. On subsequent examination, the nickel disk was found to have almost completely alloyed with the carbon and a cluster of relatively large diamonds was obtained in the position shown. In the diamond-growing region, the temperature was probably somewhat below 2,000° K., and a considerable temperature gradient existed due to thermal contact with the cold anvils. Bovenkerk *et al.*[4], describing the diamond synthesis by General Electric, mention the necessity for a catalyst metal such as nickel, and also refer to an accelerating effect of temperature gradient on diamond growth.

The diamonds obtained were black in colour. One crystal 0·3 × 0·3 × 0·4 mm. (Fig. 2), the largest synthesized in Great Britain, was examined by X-ray methods using Laue, rotation and Weissenberg diffraction photographs obtained with copper radiation. This diamond shows several well-developed crystal faces, mostly hexagonal and square. It sank slowly in cadmium borotungstate at room temperature, showing its density to be somewhat greater than 3·3 gm. cm.$^{-3}$ compared with 3·514 gm. cm.$^{-3}$ for natural diamond.

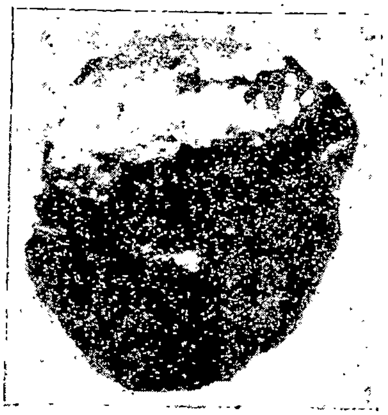

Fig. 2. Photograph of synthetic diamond showing crystal faces (× 135)

The following results show that the diamond is similar to the synthetic crystals from the General Electric Co., Schenectady, New York, which were examined by Grenville-Wells and Lonsdale[5], and by Lonsdale, Milledge and Nave[6]. A complete rotation picture taken in a 6-cm. diameter camera with filtered radiation (Fig. 3) was interpreted in terms of three separate patterns:

(*a*) The dominant pattern consists of spots corresponding in position and intensity to those from a single crystal of natural diamond rotating about $[0\bar{1}1]$ with the 'forbidden reflexions' 200 and 222 absent and weak respectively. Determinations of the *d*-spacings of the spots on the zero layer are given in Table 1 (*a*). All the spots are sharp with small spikes along constant θ arcs; the 222 spot is sharper than the others and does not have spikes showing that it may be caused by simultaneous 'Renninger reflexions'[7] from planes $\bar{1}\bar{1}\bar{1}$ and $\bar{1}33$. The main

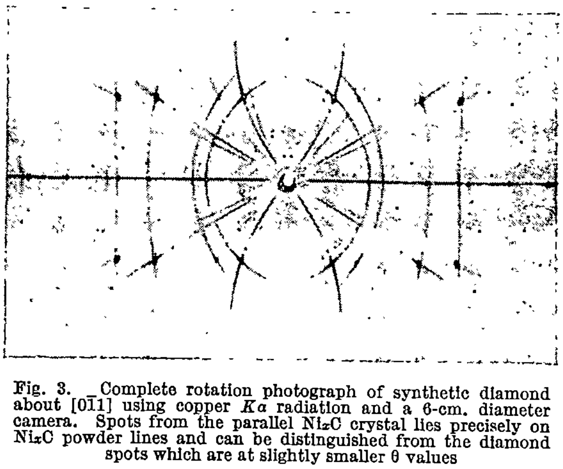

Fig. 3. Complete rotation photograph of synthetic diamond about $[0\bar{1}1]$ using copper $K\alpha$ radiation and a 6-cm. diameter camera. Spots from the parallel Ni$_3$C crystal lies precisely on Ni$_3$C powder lines and can be distinguished from the diamond spots which are at slightly smaller θ values

layer lines arise from a lattice repeat of length $a/\sqrt{2}$ where $a = 3{\cdot}565$ Å.; but there are weak subsidiary layer lines corresponding to another repeat of length $3a/\sqrt{2}$. These extra layer lines come from a small diamond crystal related to the main component by a reflexion twin across $(\bar{1}\bar{1}1)$ which brings the $[41\bar{1}]$ zone axis, with a repeat length of $3a/\sqrt{2}$, into coincidence with $[0\bar{1}1]$ (ref. 6).

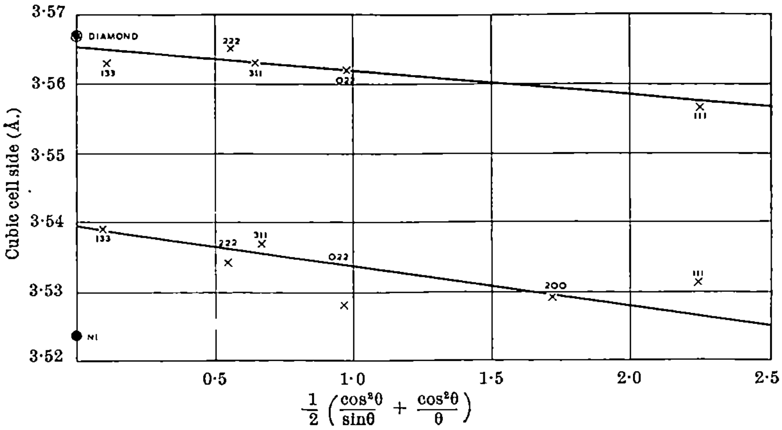

Fig. 4. Extrapolation curves giving accurate lattice parameters of diamond and Ni_xC structures. ⊙, Published lattice parameters for diamond and pure nickel; ×, experimental points with indices of reflecting planes

(*b*) There is another pattern from a cubic single crystal, also rotating about $[0\bar{1}1]$ which has a face-centred lattice exactly parallel to that of the main diamond crystal. The lattice parameter is 3·539 Å., intermediate in value between diamond (3·567 Å.) and face-centred nickel (3·524 Å.). Precise measurements show that the strong 200 and 222 spots on the photograph belong to this pattern; some of the intensity of the strong 222 spot may also arise from a double Renninger reflexion. There is no indication that this crystal is twinned across $(\bar{1}\bar{1}1)$ as in the diamond.

(*c*) A partially oriented powder pattern of phase (*b*) is present with intensities in qualitative agreement with those from nickel (Table 1 (*b*)). Careful measurements of reflexion positions were made on a random rotation photograph from an 11·46-cm. diameter powder camera, and the cell constant given by each reflexion is plotted against the usual extrapolation function in Fig. 4. It is clear that there are two separate sets of powder lines and spots confirming the presence of diamond with $a = 3{\cdot}565 \pm 0{\cdot}003$ Å., and the second cubic phase (*b*) with $a = 3{\cdot}539 \pm 0{\cdot}003$ Å. The interpretation of the smooth powder rings in the centre of the photograph is hindered by the pattern from the shellac used to mount the crystal. In a photograph taken by Dr. H. J. Milledge of another diamond from the same source, one of these smooth rings occurs alone and is almost certainly the 0002 reflexion of graphite. The occurrence of graphite with synthetic diamond is unusual.

In their study of the General Electric diamonds, Lonsdale, Milledge and Nave[6] also report the presence of a second cubic phase with $a = 3{\cdot}539$ Å., but with a different distribution of observed intensities (Table 1 (*b*)). The most important difference is in the relative strengths of the 111 and 200 reflexions. The new set of intensities is consistent with the nickel–carbon compound Ni_xC($x > 4$) (ref. 8), which has a lattice parameter of 3·536 Å. Presumably the carbon atoms are randomly arranged on octahedral sites in the face-centred nickel structure, but it is not necessary to have a random arrangement of nickel atoms as required by the previous intensity observations. It is assumed that this compound is also cubic because no deviations from cubic symmetry could be detected on Laue photographs. The compound is analogous to martensite, γ-Fe, which is a solid solution of carbon in a face-centred iron structure.

* X-ray Powder Data File (1960), American Society for Testing Materials, Philadelphia.

X-ray reflexions on the zero and first layers corresponding to rotation about the $[0\bar{1}1]$ axis were recorded with a Weissenberg camera. The pictures confirmed the results from the rotation photograph and showed the presence of two additional diamond components obtained by reflexion across the twin-planes (111) and $(\bar{1}11)$. The patterns from the twin components have no detectable satellite spots for these exposures, so if any Ni_xC compound is associated with the subsidiary twins, the amount is much smaller than that with the main diamond.

We wish to thank Dr. C. W. Bunn and Mr. W. R. D. Manning for their interest and Dame Kathleen Lonsdale and Dr. H. J. Milledge for valuable advice on and discussion of the interpretation of the X-ray data. Thanks for discussion are also due to Mr. E. A. Cole, Mr. R. P. Palmer and Miss A. Turner-Jones; and for assistance to Mr. J. Andrew, Mr. M. R. E. Ball and Mr. S. F. Bossom of Imperial Chemical Industries, Ltd. We wish to acknowledge the assistance of Mr. M. P. Littleson of the National Engineering Laboratory with the experimental details of the diamond synthesis, and of the National Engineering Laboratory Workshop for the construction of the tetrahedral-anvil apparatus.

This article is published by permission of the Director of the National Engineering Laboratory.

GEL FILTRATION OF SEA-WATER: SEPARATION OF FREE AND BOUND FORMS OF VITAMIN B_{12}

By Dr. K. W. DAISLEY*

National Institute for Research in Dairying, Shinfield, nr. Reading

When Porath and Flodin[1] published details of the separation of serum proteins from ammonium sulphate by their new technique of gel filtration, it was evident that this same method might be useful in oceanographic research, where work on the organic substances in sea-water is often hindered by the salts present.

The most sensitive microbiological assay methods for vitamin B_{12} will not function at sea-water salinity. Often, however, the sea-water can be diluted before use[2], but some oceanic waters contain amounts of vitamin B_{12} so small that dilution takes them below the measurable range. Extraction and concentration methods can be applied[3], but they need large volumes of sea-water and take much time and labour.

It was therefore hoped that filtration through 'Sephadex *G*-25' gel (Pharmacia, Uppsala) would separate vitamin B_{12} from salt, but a filter column 72 cm. × 3·6 cm. did not achieve this separation; the vitamin was delayed by the filter to about the same extent as was the salt (Fig. 1).

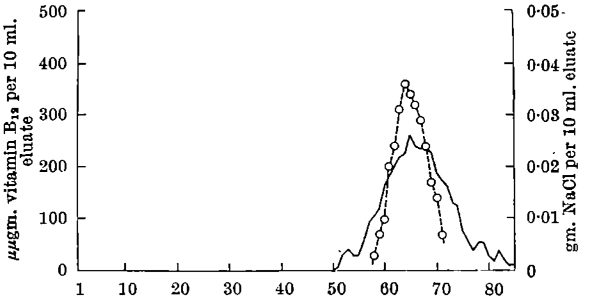

Fig. 1. Gel filtration of 10 ml. 3·5 per cent sodium chloride solution containing 500 μμgm. vitamin B_{12}/ml. Elution by distilled water. Continuous line, vitamin B_{12}; broken line, sodium chloride

There is reason for wanting to obtain separate estimates of the free and the bound forms of vitamin B_{12} in natural waters[4]. To see whether gel filtration would facilitate such separation, a binding agent prepared from pig pyloric mucosa ('Bendogen', G.E.A., Copenhagen) was added to a vitamin B_{12}–sodium chloride solution in an amount sufficient to bind half the vitamin present, and this solution was then passed through the 72 cm. × 3·6 cm. gel filter column. Free and bound forms of the vitamin were clearly separated (cf. Fig. 2 with Fig. 1), the bound form coming through first.

Gel filtration therefore does provide a simple means of separating free and bound forms of vitamin B_{12} before assay, and it can be used in obtaining separate estimates of free and bound vitamin B_{12} in fresh-water samples, and in sea-waters where the vitamin concentration is sufficiently high.

It is when the vitamin B_{12} concentration in sea-water is very low that it becomes essential to separate the vitamin from the salt, so as to permit concentration of the vitamin before assay. The result of the experiment in which a binding agent was added to the vitamin B_{12}-saline solution (Fig. 2) leads to a method of overcoming the failure of the filter to separate free vitamin B_{12} from salt. An excess of binding agent is added to the vitamin B_{12}–saline solution or to the sample of sea-water; the vitamin B_{12} present is thus converted to the bound form, which is then separated from the salt by passage through the gel filter column.

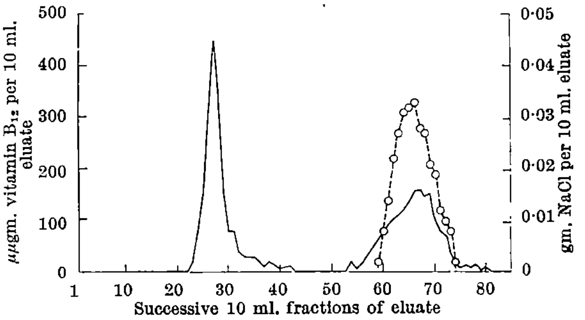

Fig. 2. Gel filtration of 10 ml. 3·5 per cent sodium chloride solution containing 500 μμgm. vitamin B_{12}/ml. and 1 μgm. 'Bendogen'/ml. Elution by distilled water. Continuous line, vitamin B_{12}; broken line, sodium chloride

After this separation, the bound vitamin, in solution in the distilled water which is used for washing it through the column, can be concentrated to the extent necessary to bring the vitamin within the range of the microbiological assay methods. For such concentration, evaporation under reduced pressure can be employed; alternatively, dry 'Sephadex' powder can be stirred into the solution. It takes up more than twice its weight of water in forming the gel, but excludes the bound vitamin B_{12}, which therefore remains in the supernatant liquid and can be poured off after centrifugation. The degree of concentration achieved by addition of the 'Sephadex' powder can be readily observed by dissolving a coloured protein (hæmoglobin) in the solution before the 'Sephadex' is added. This protein is also excluded by the 'Sephadex', and so the increase in optical density of the supernatant liquid after addition of the 'Sephadex' provides a direct measure of the increase in concentration of the coloured protein and therefore also of the vitamin B_{12}. With the degree of concentration thus known, it is not necessary to attempt the difficult complete recovery of the supernatant liquid for the purpose of the assay; measurements on a portion of the supernatant liquid can be recalculated for the whole original sample. If the dry 'Sephadex' is added by known weight, one experiment with the hæmoglobin can serve as a calibration for the whole

* Unit for Biochemical Research bearing on Fisheries' Problems (grant-aided by the Development Fund).

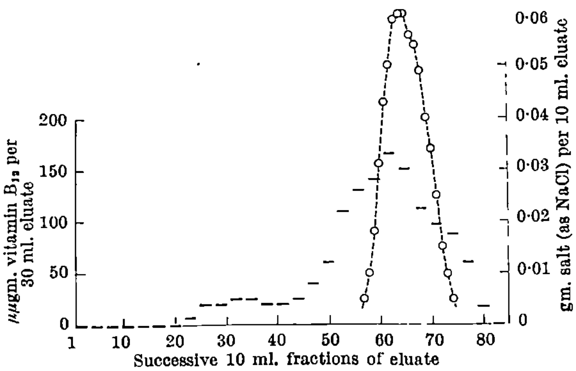

Fig. 3. Gel filtration of 30 ml. sea-water, after storage frozen since collection. Elution by distilled water. Horizontal bars, values for vitamin B_{12} content of eluate fractions combined in threes; broken line, salt (expressed as sodium chloride)

batch of 'Sephadex', and further use of hæmoglobin is unnecessary.

Figs. 3 and 4 illustrate the gel filtration technique, applied to a sea-water sample from Loch Fyne collected on February 15, 1961, by Dr. L. R. Fisher of this laboratory (the Director and Staff of Millport Marine Station are thanked for provision of collecting facilities). In this sample, the vitamin B_{12} was measurable when the eluate fractions were combined in threes; with a less-rich water, the binding agent is added and the gel filtration carried out, but then the fractions predicted to contain the vitamin (20th to 45th with this particular column) are all added together and concentrated before assay. Filtration experiments with different portions of the same water sample, with and without the addition of binding agent, provided evidence on how much of the vitamin B_{12} was originally bound.

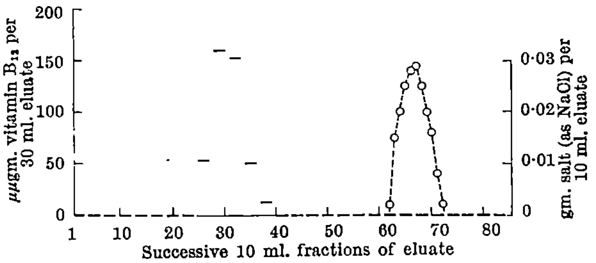

Fig. 4. Gel filtration of 10 ml. sea-water (from the same sample as in Fig. 3) + 20 ml. solution of 'Bendogen' 1 mgm./ml. Elution by distilled water. Horizontal bars, values for vitamin B_{12} content of eluate fractions combined in threes; broken line, salt (expressed as sodium chloride)

In the experiments described, vitamin B_{12} was measured by an appropriately simplified version of the *Euglena* assay previously described[2], and sodium chloride by titration against standard silver nitrate solution.

This work is being extended to other sea-waters and fresh-waters, and to microbiological culture liquors; further results will be published elsewhere.

INFLUENCE OF MOISTURE CHANGES ON DEFORMATION OF WOOD UNDER STRESS

By L. D. ARMSTRONG and G. N. CHRISTENSEN

Division of Forest Products, Commonwealth Scientific and Industrial Research Organization, Melbourne

RECENTLY it was reported[1] that creep in wooden beams was markedly increased when their moisture content changed while they were under load. In addition, it was found (Gottstein, J. W., Moglia, P. J., and Stashevski, A., private communication) that if veneers were bent to a predetermined extent and held there under conditions of either constant or decreasing moisture content, the residual deflexion after releasing the veneers was much greater in the latter case, and nearly proportional to the moisture content change over the range studied. It was considered possible that these effects resulted from interaction between the applied stress and stresses accompanying the differential shrinkage arising from moisture gradients. An alternative explanation is that the rheological properties of the wood itself were affected transiently during moisture content changes.

A distinction between these two possibilities may be made by studying very small specimens, as it has been shown[2,3] that, in specimens less than approximately 1 mm. in thickness, the rate of sorption in the absence of air no longer appears to be controlled by diffusion of moisture through the wood. Consequently, moisture changes may occur without development to the same extent of moisture gradients and stresses due to differential shrinkage of the type found in beams of larger size. (Some gradients must, nevertheless, occur within the wood cell wall as moisture movement takes place.)

The influence of changes of moisture-content on the deformation of wood under bending load has therefore been studied further using very small specimens as well as larger beams. In the present tests, the larger beams were of *Eucalyptus gigantea* of similar dimensions to those used previously (90 × 2 × 2 cm.) and were tested in an air-conditioned cabinet. The small specimens were of klinki pine (*Araucaria klinkii*, 6 × 0·1 × 0·1 cm.) and were set up in an evacuable apparatus. As well as reducing drying stresses, the use of small specimens permitted much faster, and more readily controlled, changes in moisture content. In a series of experiments, cyclic changes in moisture content were effected with the specimens loaded or unloaded as desired. Bending loads of less than 25 per cent of the short-term breaking load were used. From experiments using small beams several phenomena have been observed, and

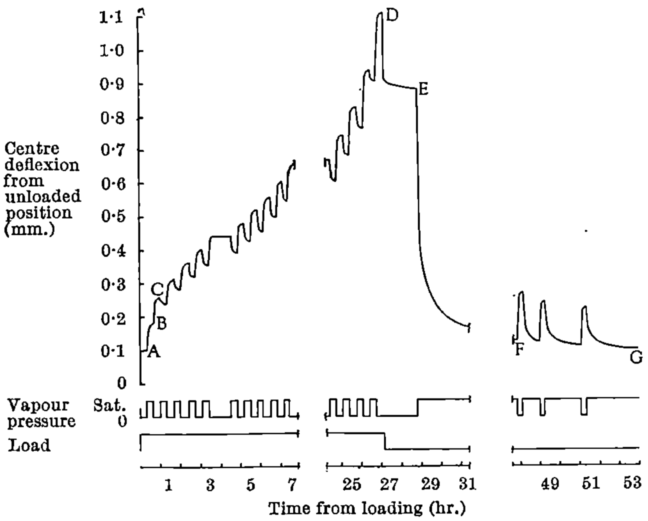

Fig. 1. Effect of changes in moisture content on bending of wood under load

these are described here. Qualitatively similar behaviour was displayed by the 2-cm. beams where-ever comparable tests were made. Some of the phenomena are illustrated by the results from one of the 1-mm. specimens in Fig. 1.

(1) When the specimen was loaded in the completely dry state, very little creep occurred within a short time of loading (Fig. 1, *0A*).

(2) If, after loading the specimen in the dry state, water vapour at saturation pressure was admitted (Fig. 1, *AB*), the deflexion increased rapidly to almost twice the initial deflexion; the rate of deflexion decreased rapidly, usually falling to a very low value within 2–3 hr. From sorption kinetics[2], it would be expected that sorption of water would have been virtually completed within this time. In the larger beams, where the sorption process was slower, similar behaviour occurred over a period of about 50 hr.

(3) When, during the first adsorption of water vapour by a loaded sample, the rate of admission of vapour to the sample was reduced (taking several hours to reach saturation vapour pressure), it was found that the final deflexion of the sample after saturation had been reached was not affected by the slower sorption-rate. In the case of the 2-cm. beams, observation of the effect of rate of change of moisture content was confined to different rates of drying from the green state, no difference being found in the final deformation reached on drying to the same moisture content over one and two weeks respectively.

(4) On re-drying the loaded specimen, the deflexion increased further (Fig. 1, *BC*), but generally by a smaller amount than during the first adsorption.

(5) During subsequent moisture content cycles, the loaded specimen showed partial recovery during each adsorption followed by increased deflexion during each desorption (Fig. 1, *CD*). Deflexions several times the instantaneous elastic deflexion were thus ultimately reached. Such large deflexions could not generally be obtained under short-term loads at constant moisture content without breaking the specimen. Similar phenomena were demonstrated by the 2-cm. beams when the moisture content was cycled between 12 and 22 per cent of dry weight.

(6) If, during moisture content cycling under load, the range of change of vapour pressure was made narrower, the changes in deflexion during each complete cycle were much less. Nevertheless, a decrease in deflexion for each absorption and an increase for each desorption were still found for each cycle after the first.

(7) If the deformed specimen was unloaded in the dry condition, little recovery other than the initial elastic response occurred within an hour (Fig. 1, *DE*). However, on admitting water vapour at saturation pressure after unloading in the dry state (Fig. 1, *EF*), a large recovery occurred.

With the 2-cm. beams, nearly half the deflexion was recovered within a month of unloading in the dry state. The greater part of the remaining deformation was recovered on soaking the beams in water for five days.

(8) When further moisture content cycling occurred after unloading, the recovery was enhanced slightly (Fig. 1, *FG*), but complete recovery did not appear to be possible by vapour adsorption and drying alone. It was noted that, during this cycling, marked changes in deflexion of the specimen occurred, whereas there were no such changes in a specimen which had not previously been loaded.

The result of these investigations is to confirm that when wood is subjected to a sustained bending load, a change in moisture content affects the rate and magnitude of deformation. Most of the change in deformation occurs within the period during which moisture content change takes place. Its magnitude depends mainly on the extent rather than the rate of moisture content change. It is not known whether these phenomena result from an acceleration of normal creep behaviour (at constant moisture content) or whether different mechanisms are involved. However, as similar effects are observed with beams of 1 mm. and 2 cm. size, stresses arising from non-uniform shrinkage are not likely to be responsible. It is possible that large transient stresses[2] are introduced into the molecular network as the moisture content changes. Under the bias of an external force, deformation may thus occur more readily for as long as the moisture change continues.

In the cycling experiments (as in Fig. 1), the decrease in deformation that accompanies all adsorptions after the first may arise from an additional process. This might be a relative change in the longitudinal components of swelling of the tension and compression portions of the beam as its deformation increases. The persistence of the effect after the deformed beam has been unloaded supports such an explanation. The large recovery obtained during the first increase of moisture content after unloading suggests that the deformed beam contains a proportion of strained but stable elements of structure sufficient to provide a restoring bias when the external force is removed.

The magnitude of the effect of the moisture content changes on deformation points strongly to the necessity for avoiding such changes not only during long-term rheological testing of wood but also during short-term mechanical testing.

DISTRIBUTION OF ISOTOPIC NITROGEN IN NITROGEN GAS DURING DENITRIFICATION

By R. D. HAUCK and D. R. BOULDIN

Division of Agricultural Relations, Tennessee Valley Authority, Wilson Dam, Alabama

NITROGEN gas, formed as a result of denitrification in soil to which isotopically enriched nitrate–nitrogen had been added, was shown[1] to retain its identity although it was evolved into a confined atmosphere already containing nitrogen gas. The atoms of nitrogen-14 and nitrogen-15 in the original atmosphere were randomly distributed among the molecules of nitrogen gas. Presumably, the atoms of nitrogen-14 and nitrogen-15 in the nitrogen gas which was formed as a result of denitrification also were randomly distributed among the molecules of this enriched gas.

However, the data presented in refs. 1 and 2 indicate that when two sources of nitrogen gas with different contents of nitrogen-15 are mixed under the conditions of ordinary biological experimentation, the nitrogen-14 and nitrogen-15 atoms in the whole mixture are no longer distributed randomly among the nitrogen molecules, because isotopic exchange among the various species of molecules does not proceed at an appreciable rate. The fact of this non-equilibrium condition was used to calculate the amount of nitrogen evolved from the substrate, as well as to allow certain inferences about the mechanism of gas formation.

Equations were derived[1] which expressed the fraction of nitrogen gas in the atmosphere which was derived from the added, enriched nitrate–nitrogen as a function of the mass spectrometric ion currents at masses 28, 29 and 30, and the atom fractions of nitrogen-15 in both the original atmospheric gas and in the enriched nitrate source. Implicit in the equations was the assumption that all the nitrogen evolved from the added nitrate–nitrogen had the same atom fraction of nitrogen-15 as the original source material. Any nitrogen from other sources which pooled with the added nitrogen and was denitrified afterwards, could not be considered accurately, once the experiment was begun.

The equations presented here permit calculation of the mole-fraction of nitrogen gas which is evolved from soil into an atmosphere containing nitrogen even though the amount of nitrogen-15 in the source material changes as a result of mixture with other soil nitrogen. The basis of these equations has already been discussed[1]. A brief restatement of some of the definitions and equations contained in that article will be appropriate here.

The mass spectrometer determines the ratios r and r', which are defined as follows: r, corrected ratio of ion currents at mass 29 to ion currents at mass 28; r', corrected ratio of ion currents at mass 30 to sum of ion currents at masses 28 and 29.

The mole fractions of the various molecular species of nitrogen are given by:

$$a + 2b + c = 1$$

where a = mole fraction of $^{14}\mathrm{N}^{14}\mathrm{N}$; $2b$ = mole fraction of $^{14}\mathrm{N}^{15}\mathrm{N}$; c = mole fraction of $^{15}\mathrm{N}^{15}\mathrm{N}$. hence:

$$r = 2b/a \tag{1}$$

$$r' = \frac{c}{a + 2b} \tag{2}$$

The nitrogen isotope fractions are represented by the following symbols: X^{14}_{N}, atom fraction of nitrogen-14 in the material undergoing denitrification; X^{15}_{N}, $(1 - X^{14}_{\mathrm{N}})$ = atom fraction of nitrogen-15 in the material undergoing denitrification; X^{14}_{A}, atom fraction of nitrogen-14 in the original atmosphere; X^{15}_{A}, $(1 - X^{14}_{A})$ = atom fraction of nitrogen-15 in the original atmosphere.

Let d be the fraction of the nitrogen gas (in the atmosphere at the time of sampling) which is derived from the isotopically enriched substrate, and let $(1 - d)$ be the fraction of the nitrogen gas (in the atmosphere at the time of sampling) which was present in the atmosphere originally.

When two sources of nitrogen gas, each with different atom fractions of nitrogen-15 randomly distributed among the molecules of nitrogen, are mixed, the resulting mole fractions are given by equations (3), (4) and (5) as functions of the atom fraction of nitrogen-15 in the two sources (X^{15}_{N} and X^{15}_{A}) and the mole fractions (d and $(1 - d)$) of the resulting mixture derived from the two sources:

$$a = (1 - d)(X^{14}_{A})^2 + d(X^{14}_{\mathrm{N}})^2 \tag{3*}$$

$$2b = 2(1 - d)(X^{14}_{A}X^{15}_{A}) + 2d(X^{14}_{\mathrm{N}}X^{15}_{\mathrm{N}}) \tag{4*}$$

$$c = (1 - d)(X^{15}_{A})^2 + d(X^{15}_{\mathrm{N}})^2 \tag{5*}$$

Equations (3), (4) and (5) can be combined and rewritten in terms only of r, r', X^{14}_{N}, X^{14}_{A} and d, as follows:

$$r = \frac{2(1 - d)(X^{14}_{A})(1 - X^{14}_{A}) + 2d(X^{14}_{\mathrm{N}})(1 - X^{14}_{\mathrm{N}})}{(1 - d)(X^{14}_{A})^2 + d(X^{14}_{\mathrm{N}})^2} \tag{6}$$

$$r' = \frac{(1 - d)(1 - X^{14}_{A})^2 + d(1 - X^{14}_{\mathrm{N}})^2}{(1 - d)(X^{14}_{A})^2 + d(X^{14}_{\mathrm{N}})^2 + 2(1 - d)(X^{14}_{A})\,(1 - X^{14}_{A}) + 2d(X^{14}_{\mathrm{N}})(1 - X^{14}_{\mathrm{N}})} \tag{7}$$

Equations (6) and (7) contain two unknowns, X^{14}_{N} and d. The value of X^{14}_{A} is obtained by direct mass spectrometric determinations of atmosphere nitrogen samples; r and r' are primary analytical data. No assumptions have been made about the source material characterized by X^{14}_{N} (or X^{15}_{N}). The symbol d specifically refers to the mole fraction of total atmospheric nitrogen which was derived from the source X^{14}_{N}.

The value for X^{14}_{N} can be obtained from the quadratic relation:

---

* Corresponding to equations (6), (7) and (8), respectively, in ref. 1.

$$X^{14}{}_{\mathrm{N}} = \frac{-B \pm \sqrt{B^2 - 4AP}}{2A} \tag{8}$$

where $A = P(r' + 1) + R(r + 2)$, $B = -2[P(r' + 1) + R]$ and $P = 2(X^{14}{}_A)(1 - X^{14}{}_A) - r(X^{14}{}_A)^2$, $R = (1 - X^{14}{}_A)^2 - r'[2(X^{14}{}_A)(1 - X^{14}{}_A) + (X^{14}{}_A)^2]$.

Using this value for $X^{14}{}_{\mathrm{N}}$, d may be calculated from the expression:

$$d = \frac{P}{(r + 2)(X^{14}{}_{\mathrm{N}})^2 - 2X^{14}{}_{\mathrm{N}} + P} \tag{9}$$

A value for d can be calculated from equations (3), (4) or (5), as well as from equation (9). The difference between the two methods of calculation lies in the fact that with equations (3), (4) or (5), as previously used[1], the value for $X^{14}{}_{\mathrm{N}}$ (or $X^{15}{}_{\mathrm{N}}$) must be measured independently at the beginning of the experiment (or from sub-samples of soil during the experiment), and may not change with time, while the $X^{14}{}_{\mathrm{N}}$ used in equation (9) is an average value calculated from mass spectrometric analysis of an atmosphere into which an admixture of gaseous components was made. If no dilution of the original and supposed source material occurs, then either equations (3), (4) or (5) or equation (9) will accurately calculate the mole fraction of nitrogen gas evolved from the substrate $X^{14}{}_{\mathrm{N}}$. However, should dilution occur, then this change in isotope content of the source material will be quantitatively reflected in the value for $X^{14}{}_{\mathrm{N}}$ as obtained (equation (8)) from the measured ratios r and r'.

12*a*	22	0·3470	0·2735	0·0364	0·0579
13	22	0·3470	0·2889	0·0114	0·0147
14	19	0·2395	0·2164	0·0514	0·0569

* Atom fraction of ^{15}N in enriched nitrate calculated from equation (8).

† Mole fraction of nitrogen evolved from source, assuming no dilution.

‡ Mole fraction of nitrogen evolved, calculated from equation (9).

Some data selected from a previous paper[3] are re-interpreted using equations (8) and (9) and presented in Table 1, to illustrate the effect of dilution of source material on the value of d obtained. Values for $X^{15}{}_{\mathrm{N}}$, that is $(1 - X^{14}{}_{\mathrm{N}})$ are also given.

The results from experiment 12*a* (Table 1) illustrate the progressive dilution of nitrate source material (characterized by the calculated value for $X^{15}{}_{\mathrm{N}}$) with time. Although it is not the object of this article to draw conclusions concerning the interplay of mineralization and denitrification reactions in soil, the observation nevertheless can be made that little dilution of the nitrate substrate was observed within the first week of incubation, whereas under the conditions of the experiments from which the data were taken, appreciable dilution occurred about two to three weeks after the beginning of incubation. The calculated value for $X^{14}{}_{\mathrm{N}}$ (or $X^{15}{}_{\mathrm{N}}$) represents the average isotope content of the material which is undergoing denitrification over a given period of time. In this respect, it approximates the composition of a composite source material integrated with time. The calculated value for $X^{14}{}_{\mathrm{N}}$ will become increasingly more important in the estimation of d as mineralized nitrogen pools with the added, enriched material. The accuracy with which the value of $X^{14}{}_{\mathrm{N}}$ characterizes the source of the evolved nitrogen gas increases as both rate of dilution and denitrification approach constancy.

In summary, the equations presented above will permit calculation not only of the amount of nitrogen gas evolved into a nitrogen-containing atmosphere as a results of denitrification, but will give as well a quantitative estimate of the relative contributions to the evolved gas by both the original source and by other nitrogen-containing material in soil from a consideration only of mass spectrometric data obtained from the atmosphere above the soil.

CALCIUM METABOLISM IN MAN WITH CALCIUM-45: MALABSORPTION SYNDROME AND EXUDATIVE ENTEROPATHY

By DR. G. MILHAUD and DR. P. VESIN

Laboratoire des Isotopes, Institut Pasteur and Service de Médecine,
Hôpital Saint Antoine, Paris

SEVERAL diseases of the small intestine are accompanied by such manifestation of impaired calcium metabolism as hypocalcæmia, hypocalciuria, tetany and osteoporosis. We have investigated changes in calcium metabolism in subjects with malabsorption syndrome and exudative enteropathy. The malabsorption syndrome (non-tropical sprue) is characterized by fatty diarrhœa and impaired absorption of several substances, including fats, carbohydrates, lipo-soluble vitamins and iron. In exudative enteropathy, described by Gordon[1] and Schwartz[2], one observes diarrhœa of variable severity, intestinal leakage of serum proteins, hypoproteinæmia and œdema; impairment of intestinal absorption is not constant.

The syndromes can be differentiated by studying the results of the intravenous injection of serum albumin-^{131}I and of polyvinylpyrrolidone-^{131}I (PVP-^{131}I). Fœcal radioactivity is marked in exudative enteropathy and negligible in sprue.

We have studied four patients with either the malabsorption syndrome or exudative enteropathy.

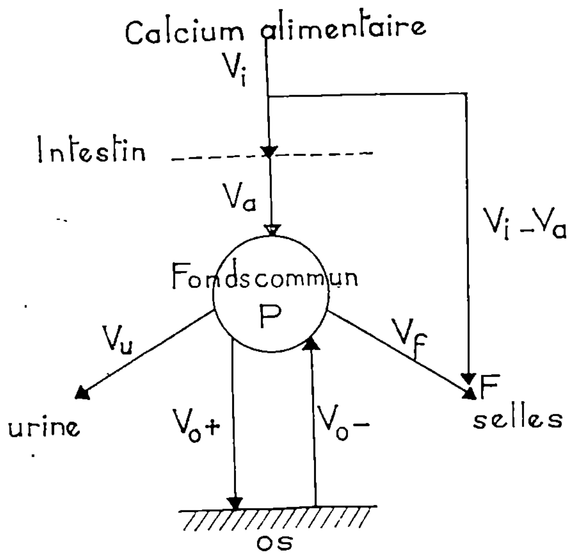

Fig. 1. Scheme of calcium metabolism

In all, radiological examination of the small intestine was typical: dilatation or hypertony of loops and dilution or scattering of barium. Two patients showed disorders of calcium metabolism.

Examination of calcium metabolism was carried out with calcium-45, using a method described previously[3,4]. Steatorrhœa was demonstrated by the triolein-^{131}I test and protein loss into the intestine was determined indirectly by means of the PVP-^{131}I test.

Case 1 (No. 110)[5]: a 31-yr.-old man, weighing 71 kgm. with exudative enteropathy. Had observed lower limb œdema and ascites for 9 yr. Total serum protein was 4·5 gm./100 ml. Steatorrhœa was marked and the PVP-^{131}I test was strongly positive. The patient complained of muscular spasms, paræsthesias and headaches. Serum calcium was 4·5 mgm. per cent, and there was marked hypocalciuria. A roentgenogram showed a calcification of the pericardium.

Case 2 (No. 121)[6]: a 14-yr.-old girl, who weighed 43 kgm., suffered from exudative enteropathy. For 6 months lower limb œdema and ascites have been present; total serum proteins were 2·7 gm./100 ml. Steatorrhœa and a very positive PVP-^{131}I test were found. The patient complained of paræsthesias and tetany; serum calcium was 6·8 mgm. per cent and there was marked hypocalciuria.

Case 3 (No. 128): a 40-yr.-old man weighing 51 kgm. had malabsorption syndrome and mild œdema. Serum protein was 5·5 gm. per cent. Marked steatorrhœa and a PVP-^{131}I test typical of exudative enteropathy were found. The oral glucose tolerance curve was flat. Serum and urinary calcium were normal and there were no clinical or radiological signs of disturbed calcium metabolism.

Case 4 (No. 117): a 70-yr.-old man, weighing 52 kgm., had experienced the onset of the malabsorption syndrome 7 months before admission. Steatorrhœa was marked and the oral glucose tolerance curve was flat. The induced hypersideræmia curve was low. The PVP-^{131}I test was normal. Serum proteins was 7 gm. per cent. There was neither œdema nor clinical or radiological signs of disturbed calcium metabolism. Serum and urinary calcium were normal.

Calcium metabolism can be represented by the scheme shown in Fig. 1. The various symbols have the following meaning: V_i, calcium ingested per time unit; V_a, calcium absorbed by the intestine; V_u, calcium excreted in the urine; V_f, calcium excreted in the fæces; V_{0+}, calcium deposited in bone; V_{0-}, calcium released from bone; Δ balance.

In addition, the exchangeable calcium pool P can be considered to include four compartments of different sizes. One corresponds to serum calcium, M, which exchanges with the calcium of the three other compartments at different rates. These three compartments can be identified respectively in first approximation as extracellular fluid calcium, M_1, exchangeable soft tissue calcium, M_2, and with exchangeable bone calcium, M_3 (Fig. 2).

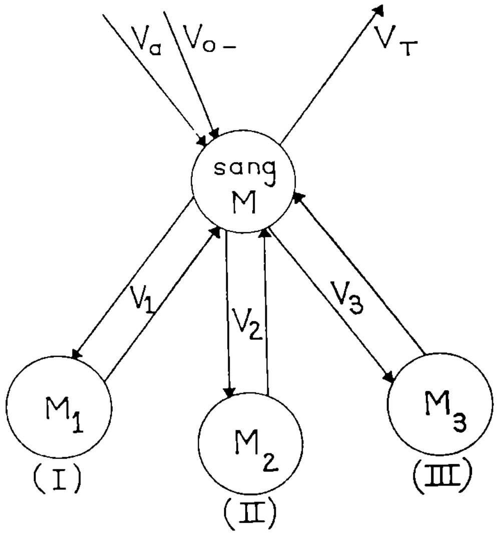

Fig. 2. The four compartments of the exchangeable calcium pool

Table 1 shows principal values of calcium metabolism for the four patients. In the first two cases, the disturbances of calcium metabolism are marked; in addition to hypocalcæmia and hypocalciuria, the values of the exchangeable calcium pool and of the rate of bone fixation represent, respectively, 50 and 60 to 70 per cent of the normal. On the other hand, the rate of osteolysis is somewhat increased, and the balance is strongly negative (– 0·544 gm./day and – 0·253 gm./day).

In cases 128 and 117, serum and urinary calcium are normal and the patients are in the balance. However, the exchangeable calcium pool and the rates of bone formation and of bone destruction are decreased.

The problems presented by the first two patients made it necessary to ascertain the role of the intestinal disease in the negative calcium balance. Intestinal malfunction may result in: (1) diminished absorption of calcium; (2) increased secretion of calcium; (3) a combination of both.

In case No. 110, the first factor applied, since no absorption of calcium could be demonstrated. However, this factor was not sufficient to account for the abnormalities found, because when the patient was studied again, following one month of weekly intramuscular injections of 15 mgm. of vitamin D, absorption became normal, but the excretion of calcium, though slightly lowered, was still abnormally

Table 1. CALCIUM METABOLISM IN FOUR PATIENTS WITH EXUDATIVE ENTEROPATHY OR MALABSORPTION SYNDROME

Number of case report	No. 110	No. 110 after vitamin D and calcium	No. 121	No. 128	No. 117
Age (yr.)	31	31	14	40	70
Height (m.)	1·76	1·76	1·61	1·72	1·67
Body-weight (kgm.)	71	81	43	51	52
Blood vol. (l.)	6·84	6·05	3·32	5·06	4·7
Plasmatic vol. (l.)	3·58	3·05	1·63	2·83	3·24

Exchangeable calcium pool (gm.)					
M	0·161	0·216	0·110	0·266	0·350
M_1	0·340	0·356	0·380	0·182	0·375
M_2	0·528	1·778	0·810	0·995	0·998
M_3	2·856	5·702	1·790	2·781	1·573
P	3·885	8·052	3·090	4·224	3·296
Intest. abs. (gm./day)					
V_i	1·062	0·814	0·633	0·908	0·829
F	1·616	0·659	0·876	0·685	0·714
V_a	0	0·507	0·237	0·358	0·282
Balance	−0·554	+0·145	−0·253	+0·002	+0·015
Abs. rate (per cent)	0	62	37	39	34
Excretion (gm./day)					
V_u	0·010	0·010	0·010	0·221	0·100
V_f	0·544	0·352	0·480	0·135	0·167
Osteoblastosis and osteolysis (gm./day)					
V_{0+}	0·540	1·788	0·630	0·510	0·713
V_{0-}	1·094	1·643	0·883	0·508	0·698

high. In case No. 121, the second factor was involved because the intestinal absorption of calcium was found to be in the lower range of normal values.

Case No. 128 also had a pathological PVP-^{131}I test, but differed from the two preceding in that the œdema and hypoproteinæmia were recent. However, his intestinal excretion of calcium was normal, a finding consistent wih the normal serum calcium and the absence of clinical or radiological signs of disturbed calcium metabolism. In case No. 117. fæcal calcium excretion was increased as compared with the normal; intestinal absorption was normal. These results are represented in Fig. 3, which shows the relation between the amount of calcium absorbed, V_a, and that excreted, V_f, by the intestine in the four patients with small intestine diseases.

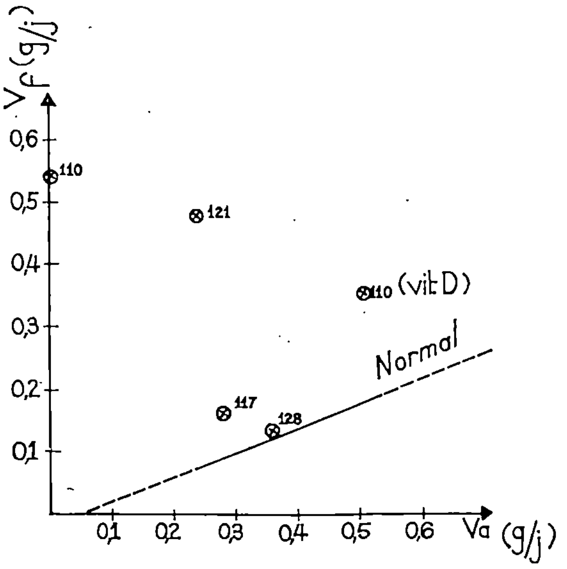

Fig. 3. Relation between the intestinal excretion of calcium, V_f, and the absorption, V_a, in the malabsorption syndrome and exudative enteropathy

It is apparent in cases No. 110 and 121 that the ratio of excreted calcium to absorbed calcium is abnormal. The case of malabsorption, No. 117, had a normal absorption and a slight disturbance of fæcal calcium excretion, observations which are consistent with the absence of clinical or radiological signs of disturbance of calcium metabolism. Table 2 summarizes the studies of absorption and excretion in the four patients.

Table 2. DISTURBANCES OF DIGESTIVE ABSORPTION AND INTESTINAL EXCRETION IN EXUDATIVE ENTEROPATHY AND MALABSORPTION SYNDROME

Case report	Absorption		Fæcal excretion of PVP-^{131}I (per cent injected radioactivity)	Absorption of calcium (gm. day)	Excretion of calcium (gm. day)	Balance
	Fat (trioleine-^{131}I) (per cent)	Carbohydrates (oral glucose tolerance test)				
110	82·5	normal	10·7	0	0·544	negative
121	51·2	normal	14·6	0·237	0·480	negative
128	50·0	impaired	5·5	0·358	0·135	balanced
117	69·5	impaired	1·2	0·192	0·167	balanced
Normal control	> 95	normal	< 1·5	0·25 to 0·50	0·100 to 0·117	balanced

The case of non-tropical sprue which Laszlo *et al.* studied using a different method showed hypocalcæmia and hypocalciuria. The fæcal excretion of calcium was very high and the ratio V_f/V_a similar to that found in our cases of exudative enteropathy. It is possible that this case, known as non-tropical sprue, was actually either a case of exudative enteropathy as the hypoproteinæmia and the high fæcal nitrogen excretion suggested, or a transition form similar to case 128, as suggested by the disturbed glucose absorption.

It should be noted that the injection of vitamin D and the oral administration of calcium profoundly changed the metabolism of calcium in case 110: the exchangeable calcium pool doubled, the rate of bone formation trebled, and the balance became positive. At the same time the paræsthesias, cramps and headaches disappeared.

We are indebted to Dr. J. P. Aubert for the mathematical analysis of the data and to Prof. Renault for the PVP-^{131}I and trioleine-^{131}I test.

USE OF RADIO-ISOTOPES IN BIOLOGICAL WORK IN BURMA

By Dr. MAUNG MYA THAUNG

Department of Agricultural and Biological Applications, Union of Burma Atomic Energy Centre

THE post-war development of atomic energy has had a tremendous impact on the thought and plans of many nations. The majority of small under-developed countries, including Burma, have been prompted to embark wisely on programmes of development with the view of enjoying the fruits of social, economic and scientific advancement which the atom might yield for humanity. Atomic energy, dedicated entirely to peaceful purposes, seems to hold the key to progress.

Burma is a recently independent neutral country with a population of about twenty million in an area of 261,789 square miles. Since nearly 75 per cent of the whole population is undernourished and disease-ridden, it seems natural and logical that an effort be made first in the domains of health and wealth, that is, in medical and agricultural applications, for producing tangible benefits in the none too distant future.

The installation at the Department of Radiotherapy of the Rangoon General Hospital early in 1958 of a 1,000-c. 'Theratron Junior' cobalt-60 (1·3 MeV.) teletherapy unit from Canada under the Colombo Plan had undoubtedly stimulated the interest of Burmese medical men (comprising one doctor for 10,000 people) in the medical exploitation of atomic energy. A few Burmese medical practitioners have made an observation tour of the United States to become acquainted with some clinical applications of radioisotopes. Furthermore, two Burmese medical graduates were awarded International Atomic Energy Agency fellowships for training in radio-isotope techniques and radiology in the United Kingdom.

The visiting radiologists were provided by Canada under the Colombo Plan until June 1960. The hospital radiotherapist and physicist on the staff of the Department of Radiotherapy were trained in Canada on Colombo Plan fellowships. The gamma unit has been doing excellent work, especially in the treatment of numerous tumour cases, mostly cancer of the mouth, pharynx, larynx, nose, breast, and cervix. Besides, both normal X-ray and radium needle facilities are available in the Department. Neither medical diagnostic nor therapeutic work with unsealed sources of radio-isotopes is performed in Burma at present.

Some pioneering work of mine was carried out on the utilization of radiation and radioisotopes as radiomutagens and radiotracers in rice plants[1]. I investigated the effects of low levels of nuclear radiations, namely, 0 r., 500 r., 1,000 r., and 1,500 r. of gamma rays from a sealed cobalt-60 source and 0 μc., 748·36 μc., 1,517·92 μc., and 2,288·54 μc. of beta rays from phosphorus-32 in a labelled fertilizer, on the development and productivity of rice plants from two varieties of Burmese rice, *C*33-18 and *D*17-88. The results obtained suggested that low levels of gamma and beta rays influenced grain yield. The intervarietal difference in response to an equal dose of the same kind of nuclear radiation was also noted.

I used a total of 18·8 mc. of phosphorus-32 in the form of ammonium dihydrogen orthophosphate imported from the United Kingdom as a tagged fertilizer to study the effect of time on grain yield and phosphorus uptake by rice plants from soil and fertilizer at three varying levels of fertilizer applications, made separately 9, 54 and 80 days after transplanting. During the first 7–9 weeks after transplanting, plants increasingly absorbed more fertilizer phosphorus than soil phosphorus; from that point onwards, the reverse was true at all levels of fertilization studied. From the ninth to tenth week the trend of relative absorption of phosphorus by plants from both sources appeared to be almost similar in spite of differences in time of fertilization. During weeks 7–9, the phosphate-supplying capacity of the soil of transplanted plot dropped to a low point, but increased after that until, during the flower primordial initiation and floral emergence stages, it reached peak values.

The best yield, found to result from fertilization 9 days after transplanting, was apparently due to an early and efficient plant utilization of more fertilizer phosphorus and also ammoniacal nitrogen, by which growth and reproduction were improved. It was suggested that fertilization with ammonium dihydrogen orthophosphate within 9 days after or during transplanting would produce beneficial effects on yield of rice.

I also initiated a radiation plant-breeding programme by having four varieties of Burmese rice, namely, *A*28-81, *B*24-92, *C*33-18 and *D*17-88 bombarded each with thermal neutron fluxes of 6·92 × 10^8/cm.^{2}/sec. and 6·70 × 10^8/cm.^{2}/sec. in the graphite reactor of the Brookhaven National Laboratory, for 15 and 20 hr., respectively. The radioactivity thus induced in the grains was allowed to become dissipated completely before return shipment. Many and varied radiobiological effects in plants of the first generation (*N*1) were recorded and reported. Transplants of *N*1 generation raised in 1959–60 were isolated by bagging to prevent cross-pollination. Similar observations and screening for seemingly useful mutants in the second generation (*N*2) were made during 1960–61. In addition, X-rays were also used at the same time to treat seeds from five other varieties of rice. Hence, *R*1 and *R*2 generations were obtained from treated seeds.

The policy of the Union of Burma Atomic Energy Centre (UBAEC) has been to co-operate with interested parties until these have had sufficient practical experience to use isotopes; the Agricultural Research Institute (ARI) has now been asked to take over radiotracer work on their own.

The International Atomic Energy Agency specialist and his co-workers have been using autoradiographic methods to estimate qualitatively the phosphate-supplying capacity of soils from ten different areas by using rice as an indicator plant. It seems that, if a soil is relatively rich in native phosphate, rice plants will absorb more soil phosphorus than added phosphorus; the reverse will be true if the native phosphate content of the soil were low.

This is an account of the practical use of radioisotopes in biological sciences in Burma so far. Attempts are being made to introduce and encourage the uses of radioisotopes in other aspects of biological research.

A COMPARISON OF COD AND BOVINE INSULINS

By Dr. S. WILSON and Dr. G. H. DIXON

Connaught Medical Research Laboratories and Department of Biochemistry, University of Toronto

THOSE mammalian insulins the structures of which have been examined are very similar and show only minor differences in amino-acid sequence[1,2], but little is known about insulins from other vertebrates.

Extracts of islet tissue from several species of cartilaginous and bony fishes have been found to possess the physiological properties characteristic of insulins prepared from mammalian sources[3]. It was therefore of interest to purify insulins from various orders of fish in order to study their properties. The work to be described yields comparisons between certain structural features of fish and mammalian insulins and provides evidence that there are large differences in the amino-acid sequences of insulins from these two classes of vertebrates.

Preparations of insulin were obtained from the principal islets of seven species of bony fish. Like mammalian insulins, these materials caused convulsions in starved mice[4] and promoted glycogen synthesis in the isolated mouse diaphragm[5]. Four of the fish insulins (from burbot, *Lota lota lacustris*; pike, *Esox lucius*; sunfish, *Lepomis gibbosus*; and sucker, *Catostomus commersoni*) were found to be immunologically similar to mammalian insulins, in that their hormonal activity was neutralized by anti-bovine-insulin sera obtained from hyperimmunized horses or guinea pigs[6]. However, the other three fish insulins (from cod, *Gadus callarias*; pollock, *Pollachius virens*; and catfish, *Ictarulus punctatus*) were very different; for example, the amount of horse anti-bovine insulin serum required to neutralize 1 unit of cod insulin was 40 times greater than that required for 1 unit of bovine, horse or whale insulins (cf. ref. 7). Because of the immunological differences between these three fish insulins and bovine insulin, it was thought likely that they might be very different chemically.

It was possible to obtain cod insulin in a highly purified state (Moloney, P. J., and Wilson, S., unpublished work) with a potency of 21 units/mgm. for the air-dried material (95 per cent confidence limits, 13–34 units/mgm.) by two mouse convulsion assays[4] using 144 animals in each test. Within the limits of the assay, this value for the hormonal activity of cod insulin is in the range, 22–26 units/mgm., reported for highly purified mammalian insulins. The fact that purified cod and bovine insulins possess similar potencies but different capacities for combining with a specific antibody to bovine insulin indicates that the groups involved in this combination need not be the same as those which determine biological activity.

When cod and bovine insulins were subjected to electrophoresis in a starch gel at *p*H 3·5 (8 *M* urea, 0·23 *M* formic acid, 0·01 *M* sodium hydroxide) the cod insulin yielded only one band which migrated faster towards the cathode than bovine insulin, as seen in Fig. 1. Paper electrophoresis of the two proteins in 5 *M* acetic acid gave a similar result. Since the cod insulin migrated more rapidly towards the cathode in both these systems, it seemed probable that it had a higher isoelectric point than bovine insulin. On partition chromatography, using the upper phase of a mixture of 2-butanol/1 per cent acetic acid as solvent, cod insulin moved only slightly from the origin ($R_F < 0{\cdot}1$) whereas bovine insulin had an R_F of 0·3. In *n*-butanol/acetic acid/water (3 : 1 : 4, upper phase) cod and bovine insulins had R_F values of 0·47 and 0·59 respectively. This is consistent with cod insulin being more polar than bovine insulin.

In order to determine whether cod insulin consisted of two polypeptide chains, such as the *A* and *B* chains of bovine insulin, linked by disulphide bonds, cod and bovine insulins were treated according to two methods which are known to split —S—S— bonds: namely, oxidation with performic acid to give the sulphonic acid form[8] and reaction with sulphite to give the S-sulpho form[9]. The products of both treatments were separated by high-voltage paper

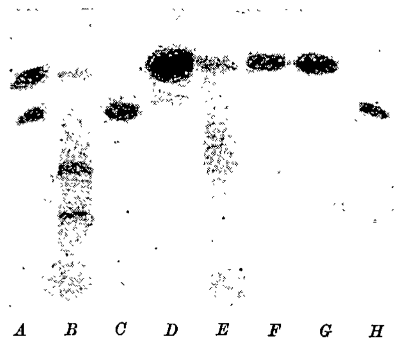

Fig. 1. Electrophoresis of various insulin preparations in starch–urea gel at *p*H 3·5 for 6 hr. at 10 V./cm. (gel stained with amido-black). *A*, artificial mixture of bonito, tunny and swordfish (BTS) and bovine insulin; *B*, pollock fish insulin (crude, 8 units/mgm.); *C* and *H*, bovine insulin (crystalline, 23 units/mgm.); *D*, BTS insulin (purified, 14 units/mgm.); *E* and *F*, cod insulin (partially purified); *G*, cod insulin (purified, 21 units/mgm.)

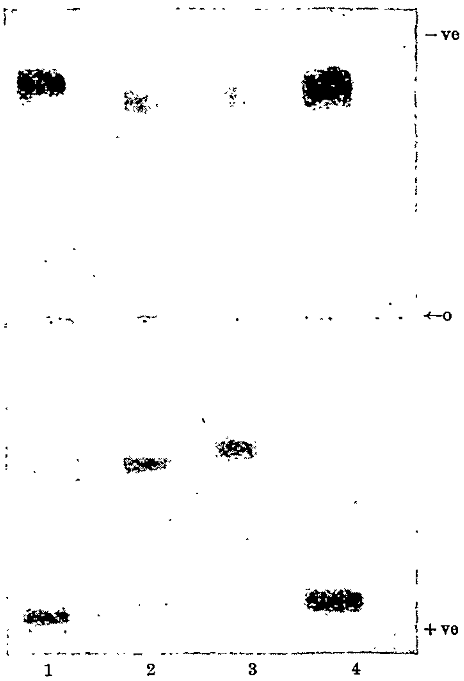

Fig. 2. Separation by high-voltage electrophoresis (75 V./cm. for 100 min.) of the *A* and *B* chains from various insulins in the sulpho- or S-sulpho-forms (ref. 7). 1, sulpho-*A* and -*B* chains from bovine insulin; 2, sulpho-*A* and -*B* chains from cod insulin; 3, sulpho-*A* and -*B* chains from BTS insulin; 4, S-sulpho-*A* and -*B* chains from bovine insulin

electrophoresis in an aqueous buffer at *p*H 4·1 containing 0·12 *M* pyridine, 1·75 *M* acetic acid and 8 *M* urea[9] or in 5 *M* acetic acid, and stained by spraying the electrophoretogram with diazotized sulphanilic acid. It was observed that cod and bovine insulins yielded two polypeptide chains in all cases, but the *A* chain from cod insulin had a much lower mobility than bovine chain as seen in Fig. 2. In addition, the spot corresponding to cod *A* chain showed the strong cherry-red colour characteristic of histidine, whereas bovine *A* chain had only the weaker orange colour due to tyrosine. The *B* chains from both insulins gave the red colour indicative of histidine, but cod *B* chain had a somewhat lower mobility towards the cathode than bovine *B* chain.

The *A* and *B* chains from cod insulin in the S-sulpho form were separated on a preparative scale by the method of Dixon and Wardlaw[9]. The solutions of the separated polypeptide chains were freed from urea and salts on a 'Sephadex' *G*–25 column (equilibrated with 0·1 *M* ammonia) and finally lyophilized. The S-sulpho *A* chains from cod and bovine insulins were hydrolysed by digestion with an aminopeptidase preparation (kindly supplied by Dr. K. S. V. Sampathkumar, Department of Biochemistry) and the resulting amino-acids identified by 2-dimensional electrophoresis/chromatography.

Histidine, arginine, phenylalanine and proline were found to be present in cod *A* chain, whereas none of these four amino-acids occurs in bovine *A* chain. Tryptophan was found to be absent from cod *A* chain, although it would have been conserved in the above procedure. For quantitative amino-acid analysis, cod insulin was oxidized with performic acid and the two chains separated by a modification of the above method[9] in which the cod *B* chain was eluted from the resin column at *p*H 3·8 with a buffer containing 2·6 *M* formic acid, 0·63 *M* pyridine and 8 *M* urea. Analyses were then carried out by Dr. D. B. Smith (National Research Council, Ottawa) on acid hydrolysates of these derivatives (5·7 *M* hydrochloric acid under vacuum for 48 hr. at 105° C.) using a Spinco amino-acid analyser and the results are summarized in Tables 1 and 2. It will be noted from Table 1 that there are considerable differences in the amino-acid composition of the *A* chains from cod and bovine insulins. One residue each of histidine, arginine, phenylalanine and proline were found in cod *A* chain, confirming the qualitative results obtained with aminopeptidase. The presence of two basic amino-acids in cod *A* chain could account for it being more basic than bovine *A* chain. Serine (2 residues) and alanine (1 residue) are present in bovine *A* chain but absent from cod *A* chain. The *A* chains also differ in the amount of glutamic acid (4 residues in bovine and 2 in cod) and aspartic acid (2 residues in bovine and 5 in cod).

The *B* chains are less unlike (Table 2), but cod *B* chain contains a residue of methionine, which is not present in any known mammalian insulin, and the threonine residue of bovine *B* chain is absent from cod *B* chain. As in the *A* chains, there is more aspartic acid in cod *B* chain (3–4 residues) than

bovine *B* chain (1 residue). Although the amino-acid compositions of the *A* and *B* chains from cod insulin differ greatly from those of bovine insulin, the total number of residues in each case is similar (last line of Tables 1 and 2).

Cod insulin was examined for N-terminal residues by the dinitrofluorobenzene method according to procedure 3 of Harris, Fraenkel-Conrat and Levy[10]. An uptake of 10·2 moles base per mole of cod insulin (based on molecular weight of 5,700) was observed during the reaction with dinitrofluorobenzene. This could be accounted for by the reaction of the lysyl, three histidyl and three tyrosyl groups known to be present, together with two N-terminal residues (total theoretical base requirement = 10·1 moles). Dinitrophenyl-serine and dinitrophenyl-glycine were found in equimolar amounts in an acid hydrolysate (5·7 *N* hydrochloric acid, 8 hr. at 105° C.) and there was no significant contamination with other dinitrophenyl-amino-acids. Since the only serine residue present in cod insulin is in the *B* chain, it must be the source of the dinitrophenyl-serine, and thus occupy the N-terminal position of this chain. The dinitrophenyl-glycine therefore came from cod *A* chain, and this was confirmed by the observation that the isolated *A* chain, like bovine *A* chain, reacted with ninhydrin to give a bright yellow colour characteristic of an N-terminal glycyl group.

Digestion of the two insulins with carboxypeptidase *A* (ref. 11) released alanine, asparagine and aspartic acid from bovine insulin but only asparagine and aspartic acid from cod insulin. Alanine was released from isolated bovine *B* chain whereas cod *B* chain yielded no amino-acid in significant amounts. However, treatment of cod insulin with carboxypeptidase *B* (ref. 12) released lysine, and since the only residue of lysine in the molecule is present in the *B* chain, it must be the C-terminal amino-acid of this chain. The asparagine residue removed by carboxypeptidase *A* from intact cod insulin therefore came from the C-terminal position of the *A* chain, as in the case of bovine insulin. It is significant that carboxypeptidase *A* does not release asparagine from either of the chains in the sulphonic acid form. In the case of bovine *A* chain, Sanger and Thompson[11] suggested that the cysteic acid residue in the penultimate position inhibited the release of the C-terminal asparagine. It is therefore probable that the C-terminal sequence in cod *A* chain is —$CySO_3H \cdot AspNH_2$ as in the bovine *A* chain.

In view of the large differences in amino-acid composition of the corresponding chains from cod and bovine insulin, certain portions of the polypeptide chains must have different amino-acid sequences. When peptic, tryptic or chymotryptic hydrolysates of the separated chains from the two insulins were compared by 2-dimensional electrophoresis/chromatography on paper, it was found that very few of the peptide fragments appeared to be the same. In Fig. 3*a*, chymotryptic digests of the *A* chains from cod and bovine insulin are compared, and Fig. 3*b* shows peptic digests of the *B* chains. Even when intact cod and bovine insulins were hydrolysed to small peptides by prolonged digestion with subtilisin (Nagase Co., Japan) the peptide maps were strikingly different.

Complete amino-acid sequences are available for insulins from seven mammalian species[1,2], and in all cases, except human insulin, the alterations in sequence occur in a sharply delineated region between residues 7 and 11 of the *A* chain. In human insulin there is an additional substitution of threonine for alanine at the C-terminal position of the *B* chain. However, the differences between cod and bovine insulins are much more profound, particularly in the *A* chain, and it is doubtful whether any of the peptic or chymotryptic peptides are identical. Zuckerkandl *et al.*[13] have reported a parallel situation in the case of hæmoglobins from a wide range of vertebrates. They found that the tryptic fingerprints of hæmoglobins from certain primates were almost identical, and had some peptides in common with those from other mammals such as ox and pig, whereas the fingerprints from three sub-classes of fish (bony fish, cartilaginous fish and lungfish) were very different from the mammalian hæmoglobins and from each other. The present results with insulins support the idea that the molecular structure of functionally related proteins becomes progressively different the greater the phylogenetic divergence between the species producing the proteins.

One of the difficulties in the present work was lack of sufficient cod insulin, and therefore methods for purification were first developed using another fish insulin which was available in large quantities (Shimizu Co., Japan), but only as a mixture from three fish (bonito, tunny and swordfish) referred to here as BTS insulin. This preparation had a potency of 14 units/mgm. (95 per cent confidence limits, 12–17 units/mgm.). Although it was a

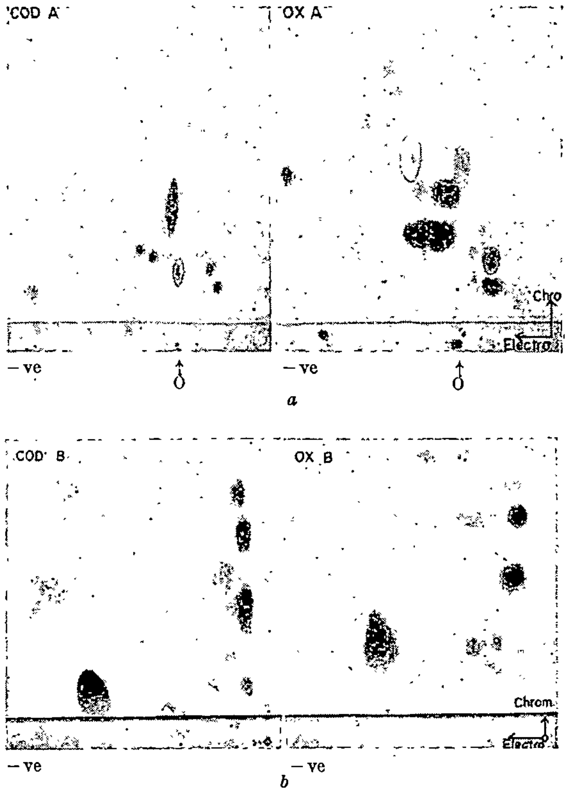

Fig. 3. Peptide maps of enzymic digests of the separated *A* and *B* chains from cod and bovine insulins. The maps were obtained by high-voltage electrophoresis on Whatman No. 3 paper in pyridine/acetic acid buffer at *p*H 3·6 followed by stitching the strip of paper bearing the peptides to another sheet for ascending chromatography in the second dimension (butanol/acetic acid/water; 3:1:1). (*a*) Chymotryptic digests of cod and bovine *A* chains in the S-sulpho form (19 hr. at 37° C. in 1 per cent ammonium carbonate solution at *p*H 8·5); (*b*) peptic digests of cod and bovine *B* chains in the sulpho form (48 hr. at 37° C. in 0·1 *M* acetic acid)

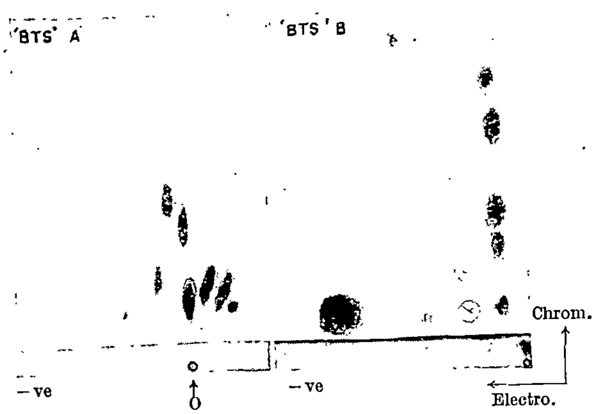

Fig. 4. Peptide maps of (left), chymotryptic digest of BTS insulin *A* chain (S-sulpho) and (right), peptic digest of BTS insulin *B* chain (sulpho-). Conditions as for Fig. 3

mixture of three insulins, the purified 'BTS' preparation behaved like cod insulin both as the intact protein (see Fig. 1) and after oxidation with performic acid (see Fig. 2). It contained two C-terminal residues, lysine and asparagine, as in cod insulin. Fingerprints of peptic and chymotryptic digests of BTS *B* chains were almost identical to those of cod *B* chain, and it is therefore likely that cod *B* chain and the three *B* chains from BTS insulin all have very similar amino-acid sequences. These findings are surprising in view of the fact that the bonito–tunny–swordfish group and cod represent two different orders of bony fish (Perciformes and Gadiformes, respectively). In contrast to the above, fingerprints of peptic and chymotryptic digests of BTS *A* chains appear to have only a few peptides in common with those of cod *A* chain, and since the total number of peptides from the hydrolysed BTS *A* chains is much greater, it is probable that the structure of the *A* chains of bonito, tunny and swordfish insulins differ among themselves as well as from cod *A* chain. Fingerprints of a chymotryptic digest of BTS *A* chain and a peptic digest of BTS *B* chain are illustrated in Fig. 4.

On treatment with dinitrofluorobenzene reagent[10], BTS insulin yielded four N-terminal residues, dinitrophenyl-glycine, dinitrophenyl-alanine, dinitrophenyl-valine and dinitrophenyl-leucine, indicating the presence of several polypeptide chains in this mixture of insulins. Yamamoto, Kotaki, Okuyama and Satake[14] have separated two insulins obtained from the bonito and showed that the N-terminal position of both *A* chains was occupied by glycine, but that one insulin had leucine at the N-terminal position of its *B* chain whereas the other had alanine.

The above comparisons of cod insulin with BTS insulin indicate that these fish insulins, representing two orders within one class of animals, have many parts of their amino-acid sequence in common but that they differ radically from insulins of another class—the mammals.

If it is assumed that the biological activity of insulin is determined by a 3-dimensional array of certain amino-acid side-chains then this specific configuration is likely to be the same for both cod and bovine insulins, since they have the same potency in a mammalian test system. Despite the similarity in potency of these insulins, it is clear that large regions of the molecule, particularly in the *A* chain, have altered in the course of evolution without changing the biological activity. Investigations of the amino-acid sequence of cod insulin are under way, and it is hoped that the establishment of those parts of the sequence which are common to this and other insulins may make it possible to suggest which regions of the molecule govern its biological action.

We wish to acknowledge the support and interest of Dr. P. J. Moloney in this work, the testing of insulin potency by Dr. A. C. Wardlaw and advice in preparation of the manuscript by Prof. C. S. Hanes. The work of one of us (G. H. D.) has been generously supported by the National Research Council of Canada.

INHIBITION BY OXYGEN OF BIOSYNTHESIS AND ACTIVITY OF NITRATE-REDUCTASE IN *AEROBACTER AEROGENES*

By FRANCIS PICHINOTY and LILIANE D'ORNANO

Laboratoire de Chimie Bactérienne, Centre National de la Recherche Scientifique, C.R.S.I.M., Marseille

CELL suspensions of *Aerobacter aerogenes* grown in the absence of nitrate acquire anaerobically a nitrate-reductase activity in the presence of this compound. The process of adaptation is due to a *de novo* biosynthesis of this enzyme from free amino-acids[1]. Moreover, the formation of nitrate-reductase induced by the ions NO_3^- or NO_2^- is greatly inhibited in aerobic cultures on a synthetic medium[2]. In the present article, we describe the effect of oxygen on the biosynthesis and the activity of the nitrate-reductase in non-proliferating suspensions of the same organism.

A. aerogenes (strain *L* III–I) is cultivated on a synthetic medium described previously[2]. Aerobic cultures are grown in Erlenmeyer flasks with agitation. Anaerobic cultures are grown in flasks under vacuum or in deep cylindrical bottles. After incubation at

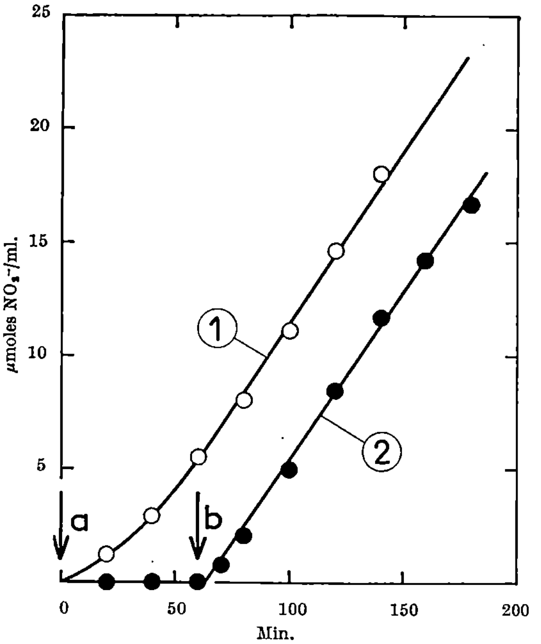

Fig. 1. Effect of aeration on the activity of nitrate-reductase. Cells: 1·5 mgm./ml. potassium nitrate is added at time 0. *a*, start of aeration; *b*, end of aeration. 1, system maintained in anaerobiosis; 2, system maintained in aerobiosis for 60 min, followed by anaerobiosis

32° C. for 22 hr., the cells are centrifuged and washed with 0·2 per cent sodium chloride. In each experiment the different systems contain the following: glucose, 50 µmoles/ml.; potassium nitrate, 25 µmoles/ml.; washed cells, 1–4 mgm. (dry weight)/ml.; phosphate buffer, *p*H 7, 0·033 *M*; temperature 37° C. Chloramphenicol is used at a concentration of 50 µgm./ml. In the adaptation experiments, 1 mgm./ml. of casamino-acids (Difco) is added. At regular time-intervals 1-ml. aliquots are taken and the nitrite assayed colorimetrically. The nitrite-reductase activity of this strain being very weak, the formation of 1 µmole NO$_2^-$ corresponds to the reduction of 1 µmole NO$_3^-$. The nitrate-reductase activity of the cells and of the extracts is determined by the rate of oxidation of a definite quantity of benzyl–viologen by an excess of nitrate, *in vacuo*, using phosphate buffer *p*H 7, 37° C., by a technique described in an earlier paper[3]. One unit of enzyme is that quantity which catalyses the reduction of 1 µmole/hr. of NO$_3^-$. The number of units contained in the cells and the extracts is reported per mgm. of protein nitrogen.

In the first part of this work, we describe the effect of oxygen on the activity of intracellular nitrate-reductase. The reduction of nitrate to nitrite in induced cells is compared under aerobic and anaerobic conditions. This experiment is carried out in the presence of chloramphenicol with a very active cell suspension derived from an anaerobic culture grown on nitrate. During aeration of the suspension, no trace of nitrite appears, but nitrite formation resumes its normal rate when aeration is stopped. Curves 1 and 2 are exactly parallel. This experiment indicates that enzyme activity is inhibited reversibly by oxygen. We have verified that aeration does not affect the stability of the enzyme. Two identical systems, one aerobic and one anaerobic, are maintained for 60 min. under conditions of the previous experiment. The cells are then centrifuged and washed. The activities of the cells and corresponding extracts measured in the presence of benzyl–viologen (Table 1) show no diminution in the course of the aeration: the intracellular enzyme retains its activity after prolonged contact with oxygen.

Table 1. EFFECT OF AERATION ON THE ACTIVITY OF NITRATE-REDUCTASE

Cell suspension	Enzyme units	
	Cells	Extracts
Anaerobiosis, 60 min.	182	75
Aerobiosis, 60 min.	187	93

In a second series of experiments, we investigated the action of oxygen on the formation of the enzyme system. The basal activity of a cell suspension of an aerobic culture grown on nitrate, measured in the presence of chloramphenicol, is practically zero (curve 2, Fig. 2). In the absence of the antibiotic, the cells acquire rapidly a high activity under anaerobic conditions (curve 1, Fig. 2). About 40 min. after the addition of the inducer, the biosynthesis of the enzyme system stops and the quantity of nitrite formed after this time becomes linear with time. Two systems identical to the preceding one are subjected to violent aeration for 60 min. After aeration, chloramphenicol is added to one. No activity is found afterwards (curve 4, Fig. 2). In contrast, in absence of chloramphenicol, adaptation begins when aeration ceases and the cells thus acquire 50 per cent of the activity of a suspension maintained constantly under anaerobic conditions (curve 3, Fig. 2). These results indicate that the adaptation of the cells is inhibited reversibly by oxygen. This phenomenon, which has likewise been demonstrated

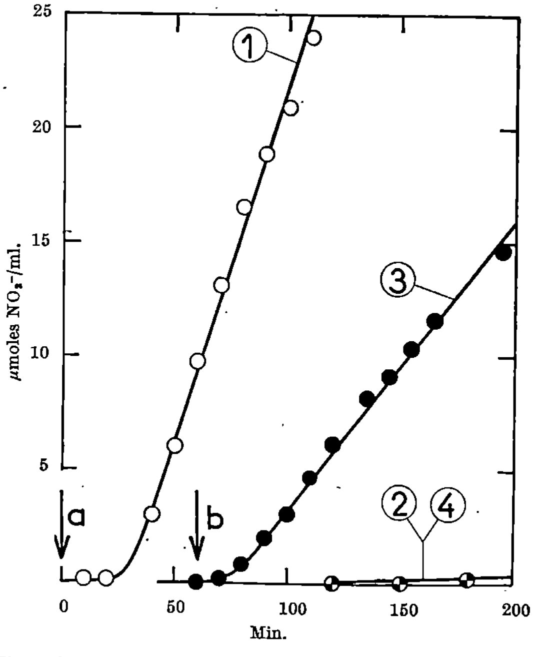

Fig. 2. Effect of aeration on the biosynthesis of nitrate-reductase. Cells: 1·5 mgm./ml. potassium nitrate added at time 0. *a*, Start of aeration; *b*, end of aeration. 1, System maintained in anaerobiosis; 2, system identical to 1 + chloramphenicol; 3, system maintained in aerobiosis for 60 min, followed by anaerobiosis; 4, system identical to 3, chloramphenicol added after 60 min. of aerobic incubation

by Pollock for *Escherichia coli*[4], can be attributed either to the inhibition of the biosynthesis of the enzymic system or to the irreversible inactivation of the system by contact with air. The experiments reported in the first part of this work definitely eliminate this second possibility. In order to confirm the previous observations, we have compared the activities of extracts of cells induced under aerobic and anaerobic conditions. This experiment is performed exactly as the one described here with cells cultivated aerobically on an ammonium chloride medium. After incubation for 60 min. in the presence of the inducer, the suspensions are cooled to 0° and chloramphenicol added to arrest protein synthesis immediately. The cells are then centrifuged and washed. The activities of the cells and extracts are measured in the presence of benzyl–viologen. The results shown in Table 2 indicate that only extracts of cells induced under anaerobic conditions have significant activity. Non-induced cells and cells induced aerobically are completely inactive. On the other hand, cells which have been incubated aerobically synthesize as much enzyme as the un-aerated suspension when anaerobic conditions are commenced. The significance of this latter experiment is clear : oxygen reversibly inhibits the biosynthesis of nitrate-reductase.

Many facultative aerobic bacteria are able to oxidize anaerobically certain organic compounds or mineral substances in the presence of nitrate and utilize the energy thus liberated for the biosynthesis of cell matter. There is reason to think that with these organisms, where nitrate replaces oxygen as the final electron acceptor in the respiratory chain, nitrate-reductase plays a part analogous to cytochrome-oxidase. It is also known that the oxidation-reduction process of denitrification is generally absent in aerobic cultures[5]. One can now anticipate that one of the causes of this important phenomenon resides in the inhibition of biosynthesis and activity of the nitrate-reductase. These investigations will be extended to true denitrifying organisms in the sense of Kluyver[5].

COMMON CARRIER SYSTEM FOR SUGAR TRANSPORT IN HUMAN RED CELLS

By DR. L. LACKO and DR. M. BURGER

Institute of Hæmatology and Blood Transfusion and Institute of Biology, Czechoslovak Academy of Science, Prague

THE interesting findings of Heinz[1,2], who described the counterflow transport of amino-acids in Ehrlich ascites carcinoma cells, made it possible to study transport systems across the cell membrane from a new point of view. By applying this concept to the study of the mechanism of sugar influx into cells (for example, erythrocytes), transport systems common to various sugars can be determined.

We are presenting some facts to prove that, whereas one group of sugars is transported into erythrocytes by an identical carrier system, another group is not. Two experimental observations form the basis of our work. (1) It has been proved that red cells are capable of exchanging sugars such as glucose–mannose by the counterflow mechanism[3]. (2) Counterflow transfer can be distinguished from normal transport (without exchange) by incubating erythrocytes at a lower temperature (0° C.) at which, as has been shown, exchange transfer prevails. At 0° C. a marked influx of sugar into red cells only occurs if another sugar leaves the cells simultaneously[4].

Human blood was collected into an *ACD* (trisodium citrate 1·1 gm.; citric acid 0·4 gm.; glucose 3·5 gm.; water 100 ml.) solution and left at room temperature for 30 min. to allow for the entry of glucose into erythrocytes. The red cells were separated from the plasma by centrifugation; 1 ml. of the packed red

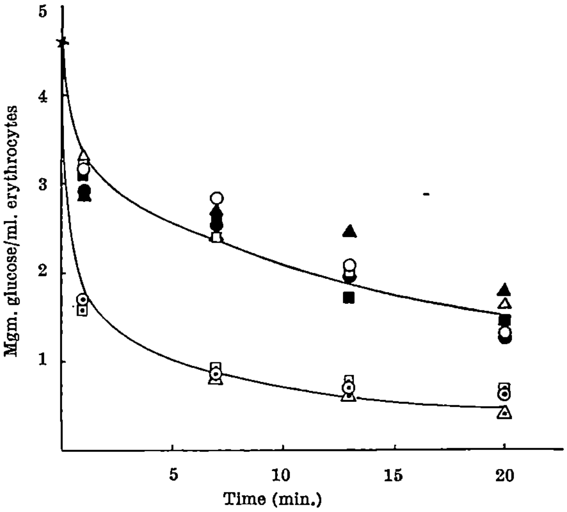

Fig. 1. Content of glucose in erythrocytes during incubation of glucose containing cells in media with different sugars.

×, level of glucose in erythrocytes at the beginning of the experiment. Content of medium: ○, 0·90 per cent sodium chloride; □, 0·98 per cent sodium chloride; △, L-sorbose; ●, D-fructose; ■, D-arabinose; ▲, D-ribose; ⊙, D-galactose; ⊡, D-mannose; ◬, D-xylose.

The sugars were present in the media in concentration 2·8 × 10^{-2} *M* dissolved in 0·90 per cent sodium chloride

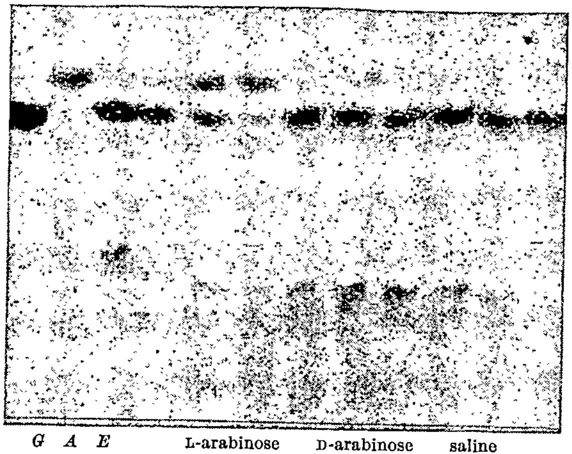

Fig. 2. Content of sugars in erythrocytes during incubation of cells containing glucose in L- and D-arabinose. The first two columns represent standards of D-glucose D- and L-arabinose; *E* represents content of glucose in erythrocytes at the beginning of the experiments. The following columns represent the amount of sugars in red cells after various time (min.) of incubation in L- and D-arabinose and saline

cells was incubated at 0° C. in 10 ml. of a 2·8 × 10^{-2} *M* solution of sugars in 0·90 per cent sodium chloride and, in a control experiment, in a sugar-free solution of 0·90 per cent and 0·98 per cent sodium chloride, respectively. At various time-intervals the sugar content of the red cells was determined by the process described in ref. 4. Fig. 1 shows that glucose leaves the red cells rapidly if D-galactose, D-mannose and D-xylose are present in the medium; however, in the presence of D-fructose, L-sorbose, D-arabinose and D-ribose the efflux of D-glucose is considerably slower, as it is into media containing sodium chloride only. By means of paper chromatography[5] we found that if the glucose efflux from the red cells was fast the sugar present in the medium appeared simultaneously in the red cells instead of glucose and that the sugar influx corresponded approximately to the glucose efflux.

The chromatogram (Fig. 2) shows an example of the substitution of glucose by another sugar (L-arabinose) in the red cells; yet another sugar (D-arabinose) does not have this effect, so that during the experiment the glucose-level in the red cells remains unaltered whether they are incubated in D-arabinose or in saline.

Similar experiments showed that there are two groups of sugars, one of which (D-galactose, D-mannose, L-arabinose, D-xylose, D-lyxose, 2-deoxy-D-glucose, 2-deoxy-D-galactose) enters the erythrocytes at 0° C., whereas another group of sugars (D-fructose, L-sorbose, D-arabinose, D-ribose, L-rhamnose, L-fucose) does not enter the red cells under these conditions.

It can be assumed that the first group of sugars shares the same carrier system when entering the red cells, and that this system is not identical with that used by the other group of sugars. We were interested to ascertain whether the second group, though not using the same carrier system as the first group, has not one carrier system in common as well. However, on using erythrocytes containing sorbose, we did not observe any exchange of this sugar by D-fructose, D-ribose and D-arabinose.

A comparison of the structure of the sugars investigated showed that aldoses using the same carrier system have one structural property in common, in that they belong to the homomorphous series of sugars with L-arabino, D-xylo and D-lyxo configuration, whereas sugars of the homomorphous series with D-arabino, D-ribo and L-lyxo configuration do not have this carrier system in common. This does not hold for ketoses, judging from the fact that D-tagatose, which belongs to the homomorphous series with the D-lyxo configuration, nevertheless did not replace glucose in our experiments. Our results are partly in keeping with LeFevre's[6] conception that the greater the affinity of sugars to the carrier system, the greater the stability of sugars in the C-1 conformation[7]. However, our results suggest that there is no gradual transition between the two groups but a sharp division, the first group having the same carrier system in common whereas the other has not. It is also important to note that glucose was substituted in our experiments by D-lyxose but not by D-ribose although, according to LeFevre, the former has a higher dissociation constant in the carrier complex than D-ribose[6].

Our thanks are due to Mrs. L. Hejmová and Mrs. H. Kopecká for technical help and to Dr. M. Černý for valuable criticism and for the gift of some sugars.

STEROL REQUIREMENTS OF THE SILKWORM, *BOMBYX MORI*

By Dr TOSHIO ITO

Sericultural Experiment Station, Suginami-ku, Tokyo

In a previous paper[1] I showed that soybean oil was necessary for the sub-optimal growth of the silkworm, *Bombyx mori*, and that no larva reached the second instar without oil, so far as the diet, containing 10 per cent mulberry leaf powder, 14 per cent cellulose powder, and other nutrients such as sucrose, soybean casein, and inorganic salts, was used. Subsequent experiments[2] showed that the effect of soybean oil could be attributed principally to the unsaponifiable matter, and not to fatty acids of the oil. In this connexion, the nutritive effects of sterols were tested recently and it was proved that silkworm larvæ required them for growth and development. The present communication gives a preliminary account of the results.

For testing the effect of sterols, artificial diets were used. The methods of preparing the diets and of rearing the larvæ have already been described[1,2].

The composition of the diet is presented in Table 1, which is somewhat improved on that used in an earlier work[1]. The vitamin mixture employed is shown in Table 2. The amount of sterol added was 1 mgm. to each 1-gm. dry diet. Rearing was carried out in a Petri dish, as shown previously, 20 larvæ for each dish, in duplicate. All tests were started with newly hatched larvæ, and dishes were kept at 25° C. The criteria used determining efficiency of a diet were the increase in weight and the number of larvæ which reached through various instars in 17 days.

All the tests with sterols were carried out in combination with soybean oil (4 per cent), since the presence of the latter substance enhanced feeding greatly, while the addition of some of the sterols used, and no oil addition, resulted in the reduction of the feeding. The results obtained are summarized in Table 3.

On the control diet without sterol, most of the larvæ reached the second instar, because of the presence of 4 per cent oil. The effect of the oil at varying concentrations has been presented already[2]. Those larvæ growing on such a diet deficient in sterol eventually died without reaching the third instar. However, the addition of sterol to the diet had a marked positive effect on the rate of growth. Such an effect varied with different sterols ; most noticeable with either β-sitosterol or stigmasterol, intermediate with cholesterol, and rather poor with ergosterol. When the diet contained approximately 0·1 per cent additional β-sitosterol, silkworm larvæ increased their weight most and reached the fourth instar rather sooner, and the lowest mortality occurred. Almost similar effects were obtained with one of the phytosterols, stigmasterol.

Table 1. COMPOSITION OF THE DIET

Substance	Amount used (gm.)	Dry diet (per cent)
Mulberry leaf powder	0·6	10
Starch (potato)	0·9	15
Sucrose	1·2	20
De-fatted soybean casein	1·2	20
Soybean oil (unrefined)	0·24	4
Wesson's salt mixture	0·06	1
Cellulose powder (General Biochemicals, Inc., Ohio)	1·8	30
	6·00	100
Vitamin mixture	2·37 mgm.	
Sterol, where necessary	6 mgm.	
Distilled water	9·0 ml.	

Table 2. COMPOSITION OF THE VITAMIN MIXTURE

Vitamin	Amount added to 6 gm. dry diet (μgm.)
Biotin	10
Calcium pantothenate	100
Choline chloride	1,000
Folic acid	10
Inositol	1,000
Niacin	100
Pyridoxine hydrochloride	50
Riboflavin	50
Thiamine hydrochloride	50
Total	2,370

All vitamins, except for choline chloride and inositol, were kindly supplied by Dr. G. S. Fraenkel, Department of Entomology, University of Illinois.

Table 3. EFFECT OF STEROLS ON GROWTH, DEVELOPMENT AND SURVIVAL OF THE SILKWORM

Number of larvæ reached through various instars in 17 days, out of 20 newly hatched larvæ (mean of two batches)

Sterol	Second instar	Third instar	Fourth instar
Nil	17·5	0	—
Cholesterol	18·5	13·0	3·5
Ergosterol	18·0	6·5	0
β-Sitosterol	17·5	17·0	14·5
Stigmasterol	19·0	17·5	11·0

Number and average weight of surviving larvæ, out of 20 (mean of two batches)

Sterol	After 14 days		After 17 days	
	No.	Weight (mgm.)	No.	Weight (mgm.)
Nil	1·0	6·6	0	—
Cholesterol	14·0	16·5	12·5	28·6
Ergosterol	8·0	7·7	4·5	7·7
β-Sitosterol	18·0	43·4	17·0	82·0
Stigmasterol	17·5	30·6	15·5	49·5

β-Sitosterol was purchased from Nutritional Biochemicals Corp., Ohio, and other sterols were kindly supplied by Dr. H. Lipke, Army Chemical Center, Maryland

The requirements for sterols in insects have been well established and several reviews on this subject are available[3]. So far investigations show that no insect exists which does not require a dietary source of sterol. Nevertheless, the majority of such data is based on the experiments with non-phytophagous insects, and sterol requirements in leaf-feeders have seldom been analysed. Though the testing period in this work is limited to a certain period of life of the silkworm, it is evident that the silkworm requires sterols for growth. Cholesterol has been used in common in investigations concerning nutrition of insects, but it has been shown that in some forms other sterols can be substituted for cholesterol. The effectiveness of substitution varies depending not only on the insect species under investigation but also on the kind of sterols tested. In some insects it has been reported that phytosterols must be used at a higher concentration in the diet, when substituting cholesterol for them. In the silkworm β-sitosterol and stigmasterol were more effective than cholesterol. The effectiveness of cholesterol might be reduced, at least partly, by its retarding or inhibitory effect on feeding (Ito, T., unpublished work).

One of the components of the test diet, mulberry leaf powder, contains phytosterols[4,5], which have also recently been extracted in a crystalline form by me from mulberry leaves. Furthermore, soybean oil added as one of the ingredients contains phytosterols. However, it is clear that the quantity of sterols from both sources only is not enough for further growth beyond the second instar. The formula $C_{27}H_{46}O$ was suggested for mulberry leaf sterol some thirty years ago, and another one later[5]. However, this must be re-investigated, in view of recent progress in steriod chemistry. Mulberry sterols were also of positive nutritive effect for the silkworm (Ito, T., unpublished work).

Further details will be published in *the Bulletin of the Sericultural Experiment Station.*

PATTERN OF PYRETHRIN-RESISTANCE IN HOUSEFLIES

By B. C. FINE

London School of Hygiene and Tropical Medicine, Keppel Street, London, W.C.1

IN 1953, Busvine[1] found that a strain of houseflies, selected for resistance to paralysis (knockdown) induced by DDT, had its tolerance to Pyrethrum raised incidentally to a level of 11·5 times the normal. Correlations between DDT- and pyrethrin-resistance have since been reported in bed bugs[2] and the tick, *Boophilus decoloratus*[3]. It appears that in some circumstances resistance to the two insecticides is related.

In order to gain a wider understanding of pyrethrin-resistance and its associations with DDT-resistance, selection experiments and toxicological work have been carried out on three strains of houseflies. One strain, the Swedish, was provided by Mr. J. Keiding in 1959. By 1956 these flies had developed resistance to many of the chlorinated hydrocarbons and parathion. Synergized pyrethrins were then used to control the flies, but in 1958 it was reported that they had become resistant to Pyrethrum and synergized Pyrethrum. The levels of resistance were respectively 11–14 times and 10·7 times that of a susceptible strain[4]. The second strain originated in Omdurman, Sudan, where it developed high levels of resistance to γ-BHC and related compounds[5]. The third strain was a normally susceptible strain.

The flies were reared according to standard techniques and toxicological measurements were made by topical application of a measured drop (0·34 μl.) to the back of the thorax of female flies[6]. The insecticides were dissolved in either Shell Risella oil or di-(2 ethylhexyl) phthalate (DOP), which are non-volatile solvents. The use of volatile solvents such as acetone is known to exaggerate the measure of resistance to DDT appreciably[7]. Preliminary tests carried out on the Swedish strain showed that resistance to Allethrin in acetone was approximately eight times the level recorded for Allethrin dissolved in Risella oil. In Table 2 it will be seen that resistance-levels for Allethrin and Pyrethrum in Risella and DOP are not the same: when compared to Risella oil, the use of DOP tends to exaggerate resistance to certain pyrethroids by a factor of approximately two. In view of the fact that toxicity varies according to the nature of the solvent, caution should be exercised in comparing the results presented here with those of other authors who employed different techniques. Susceptibility to knockdown was determined by exposing female flies to dry residues of DDT applied to glass surfaces at a rate of 0·01 mgm./cm.[2,8].

The Swedish strain was inbred and then selected for resistance to Pyrethrum over eight generations. Selection was carried out by topical application. The Omdurman strain was selected over 23 generations for resistance to knockdown by DDT. In this case the DDT-treated glass surfaces acted as the selective agent. In Table 1 the effects of these selection procedures are presented. During the last stages of selection, the toxicity of various pyrethroid and non-pyrethroid insecticides was measured by topical application against the Swedish, Omdurman and susceptible flies. The results are presented in Table 2 and illustrated in Fig. 1. The results are expressed in terms of LD_{50} (median lethal dose) or KT_{50} (median knockdown time). These values were estimated from log-dose probit lines. Insecticides dissolved in Risella or DOP are indicated in Fig. 1 and Tables 1 and 2 by the symbols (*R*) and (*D*) respectively.

Table 1. EFFECTS OF SELECTION ON THE SWEDISH AND OMDURMAN STRAINS

	Swedish		Omdurman		Increase in resistance as a result of selection*	
	Before selection	After 8 generations of selection with Pyrethrum	Before selection	After 23 generations of selection with DDT	Swedish	Omdurman
LD_{50} μgm./fly Pyrethrum (*R*)	3·6	14·3	0·54	11·9	3·9	22
LD_{50} μgm./fly DDT (*R*)	>10·2	>10·2	2·7	>10·2	No measurable loss in resistance	>3·7
KT_{50} hr. DDT	—	>24	0·8	>24	—	>30

* Represented by ratio: $\dfrac{LD_{50} \text{ or } KT_{50} \text{ after selection}}{LD_{50} \text{ or } KT_{50} \text{ before selection}}$

The results presented in Table 1 show that selection with Pyrethrum in one strain and with DDT in another each serve to raise resistance to Pyrethrum. Furthermore, the patterns of resistance to pyrethrins and related compounds as illustrated in Fig. 1 are similar, suggesting that the type of Pyrethrum-resistance in the two strains is fundamentally the same. It may be argued that the apparent correla-

Table 2. MEDIAN LETHAL DOSES IN μGM. PER FLY OF VARIOUS INSECTICIDES FOR THE SUSCEPTIBLE, SWEDISH AND OMDURMAN STRAINS

Insecticide	LD_{50} μgm./fly			Level of resistance*

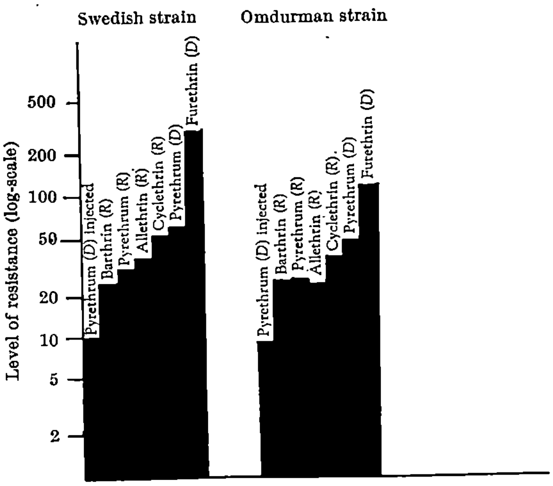

Fig. 1. Patterns of pyrethrin-resistance in two strains of houseflies

tion between DDT- and pyrethrin-resistance in the Swedish strain has resulted from prior use of both insecticides in the field. However, a definite relationship between resistance to the two insecticides is shown here for the Omdurman flies, which were susceptible to Pyrethrum and only moderately tolerant to DDT before selection was initiated (Tables 1 and 2). The nature of this relationship remains obscure. It could be dependent on a single mechanism of resistance which acts with equal facility against either insecticide. Such a mechanism is unlikely to be related to the activity of the enzyme DDT-dehydrochlorinase because DDT and pyrethrins are chemically very different. An alternative explanation for the association between DDT- and pyrethrin-resistance is that there are separate resistance mechanisms which have a correlated genetic basis in the form of pleiotropism, modifying genes or closely linked genes. However, it is doubtful whether the same complex genetic apparatus would be responsible for DDT- and pyrethrin-resistance occurring together in different species.

The two resistant strains are also more or less resistant to dieldrin and malathion. Dieldrin-resistance, being greatly different in the two strains, is probably not related to pyrethrin-resistance. Tolerance to malathion in both strains may be due to previous use of this insecticide in the field.

The results presented here also provide some preliminary information about the nature of pyrethrin-resistance. The high levels of resistance obtained for Pyrethrum and the synthetic pyrethroids are indicative of physiological resistance rather than 'vigour tolerance'. Lethane, an organic thiocyanate, is chemically unrelated to any of the other insecticides used. Resistance to Lethane can, therefore, be used as a measure of 'vigour tolerance'. Tolerance to this insecticide is of a low order in both resistant strains, and therefore the contribution of non-specific factors to pyrethrin-resistance is negligible. The high order of resistance to Pyrethrum in the Swedish and Omdurman strains is greatly reduced when measured drops of the insecticide are injected into the flies instead of being applied to the back of the thorax (Table 2). This does not necessarily indicate that the cuticle of resistant flies is less permeable to insecticides than the integument of susceptible individuals. The loss of resistance on injection may be due to a sudden flooding of the protective mechanism of resistant flies[9]. Alternatively, the protective mechanism may be concentrated in the cuticle and is by-passed on injection.

It will be observed from Fig. 1 and Table 2 that resistance to Pyrethrum extends to all the pyrethroids tested. It would appear that the same defence mechanism can cope with all these insecticides. It is also noteworthy that the highest levels of resistance are obtained for the two compounds, Cyclethrin and Furethrin, which do not have an open side chain to the keto-alcohol.

Further genetic, biochemical and toxicological work is being undertaken in order to investigate some of the problems raised in this article.

This work was supported in part by a grant from the South African Council for Scientific Research while I was holder of a Union Postgraduate Scholarship from the University of the Witwatersrand, Johannesburg. The Pyrethrum Board of Kenya and Mitchell Cotts and Co., London, supplied samples of Pyrethrum. Allethrin, Barthrin, Cyclethrin and Furethrin were supplied as samples of commercial products by McLaughlin Gormley King Co., Minnesota.

ARTHROPOD TRANSMISSION OF MICRO-ORGANISMS

By Dr. JOHN MACLEOD

Field Research Laboratory, Animal Health Division, Ministry of Agriculture, Blackford, Carlisle

IT is becoming increasingly difficult to treat as separate subjects the propagation of a micro-organism which is acting as an animal or plant pathogen and the similar propagation of one not causing disease. There is a growing need for a common terminology, but, until our knowledge of microbial biology has expanded very considerably, it is not likely that agreement about this will be reached. In the meantime we can at least so define some of the terms in present use that they can if necessary be applied without further *ad hoc* definition outside the particular field for which they were coined. The terminology of biological transmission of disease agents by arthropods has now reached a stage where precise definition and some revision are necessary. The reasons for these and the rationale of a suggested system are given here in the hope that they may help to form the basis of an agreed terminology in which a term means what it says, and can so be used irrespective of the precise context.

The usual division of transmission mechanisms is into mechanical and biological. The distinction between these has been variously interpreted as either or both multiplication of the agent within the arthropod and existence of an extraneous incubation period of the disease; different interpretations of what constitutes multiplication within the vector, and even the acceptance of simple invasion of the vector tissue prior to transfer as sufficient criterion for biological transmission, have further confused a classification at no time adequately defined, and now untenable as a simple dichotomy in the light of modern knowledge. Day[1], reviewing the mechanisms of arthropod transmission of viruses, suggested that "the cyclopropagative type best describes most examples of biological transmission of viruses by arthropods". This, however, begs the question of defining the limits of the biological type. In the following proposed scheme this time-hallowed term has been dropped as a description of a defined category.

We could usefully take the two terms 'horizontal' and 'vertical transmission', suggested by Gross[2] for transmission of a pathogenic agent, as describing the limiting conditions. 'Horizontal' means spread between contemporaries, that is, from one host to another, usually of the same generation, whether by contact, by fomites, or biological being immaterial. 'Vertical transmission', on the other hand, is from one generation to the next in the same line, that is, hereditary, though not genetically inherited. Pathogenic agents thus transmitted from host to offspring are often latent, and their presence may be unsuspected until circumstances upset the host–microbe equilibrium, or horizontal transmission occurs to another host, and disease results. Such agents may enter a spell of horizontal propagation before reverting to the vertical mode. It thus seems theoretically possible for the same organism to have a strictly hereditary (vertical) mode of transmission, and a strictly infectious (horizontal) mode, and to oscillate irregularly between, as, for example, with the phages[3].

Between these limiting types of transmission there are the types which involve two host species—the ziz-zag transmission of Andrewes[4]. It is with these I am mainly concerned here, but Gross's terms are useful not only in defining the extremes of the range of propagation methods but also in helping to clarify our appreciation of the fundamental differences between these extremes. In horizontal transmission it is not of immediate importance—to the organism—whether or not the host be killed. In vertical transmission the organism obviously must not kill its host, at least until the next generation is established; it is generally avirulent or inactive. In vertical transmission the microbes might indeed be regarded as disease agents 'looking for a disease', but because of the possibility of oscillation of their mode of transmission they cannot be ignored, even by the specialist interested only in the 'disease' reaction of the definitive host to infection.

The concept is so useful that where the terms can be adapted to the special case of arthropod transmission, without doing violence to their original definition, there is a case for using them.

Types of Transmission

Excluding the accidental type of transference arising from surface contamination, for example of the feet or proboscis of the insect, eight types of process or sequence can be recognized in significant transmission of disease to vertebrates by arthropods which actually ingest the infected tissue; they are probably equally applicable in the case of plant hosts:

(1) *Mechanical.* This may be by direct inoculation (flying needle), as in myxomatosis, or indirect, by contamination, for example by regurgitation or defæcation on food, as with poliomyelitis and flies. There need not be multiplication in the vector, and the duration of infectivity is often quite short. This type probably includes groups I and II of Watson's[5] list of plant viruses.

(2) *Simple multiplicative.* For example, plague bacilli in fleas. This may also be the type occurring in lice infection with *Rickettsia quintana* of trench fever, that is, there may even be an 'extrinsic incubation period' before transmission of the organism is possible. Nevertheless, this should be regarded as direct transference from host to host, on the grounds that the organism does not dwell in the vector tissue. Multiplication is only incidental to the sojourn in the shelter of the vector's intestinal tract, and is not essential, since theoretically the original units themselves might cause the infection of the new host. Some of Watson's group III viruses are probably transmitted in this manner, although some, and all his later, groups belong to my next main category.

The transmission in these two types is strictly horizontal in the sense that Gross uses the term, and it is suggested that, for arthropod transmission, the term be used to separate them from the second main category, in which the organism invades the tissue of the vector.

In other cases the organism may become more intimately associated with the vector. Invasion of the tissue occurs, and the association, so far as the original units are concerned, may be regarded as the end of the journey, instead of the mere sojourn it represents in horizontal transmission. Multiplication of the organism within the tissues of both hosts is probably necessary to propagation, and Andrewes's term 'zig-zag' is suggested as a comprehensive term for this class of transmission. The term is less confusing than 'developmental transmission', since this has been used also for transmission involving development of the vector from the infected instar to the next before it becomes infective.

These 'zig-zag' transmission sequences might be encompassed within one stage of the vector's life-history (intra-stadial); may involve stage-to-stage survival, or the organism may survive throughout a complete stage, for example from the infected larva of a fly through the pupa to the infective adult. The term 'trans-stadial' is probably the most useful for this last. Unfortunately, this term has also been used, wrongly, for stage-to-stage, that is, implying 'trans-moult' only. The confusion is not restricted to comparison of descriptions by different writers; in a recent American paper the term was defined early in the article as meaning passage of disease agents between active stages of a vector, and used later in the same article to refer to passage from the larva to the female tick, that is, across a complete intermediate stadium.

For the above three types the following names are suggested:

(3) *Intra-stadial transmission.* The infected stage becomes infective. For example, the products of intra-cellular multiplication of *Rickettsia prowazekii* in the epithelium of the louse gut may result in the fæces of the same instar becoming infective. Classical examples are the mosquito-malaria and tsetse-trypanosomiasis associations.

(4) *Stage-to-stage transmission.* That is, one stage becomes infected, the next infective. This accepted term is clear and convenient, and only for adverbial use would a single term be more convenient: 'ecdysial' might serve. This type is common in arthropods which have one meal per stadium, for example three-host ticks.

In this and the following types it is assumed that multiplication of the organism occurs in the vector. It may happen that among the Protozoa, and possibly the *Rickettsiae*, there is elimination of all the ingested elements except a limited number which survive either because of their stage of development or by accident of their location; these could conceivably remain in a non-multiplying form for long periods, but an ultimate phase of multiplication seems an unavoidable precursor to infectivity. With the viruses, multiplication has been demonstrated in, for example, Colorado tick fever, and it is probably a safe assumption that this must usually occur in the vector, in view of the die-away rate to be expected and, in the case of ticks, of the long periods usually involved in metamorphosis.

When stage-to-stage transmission occurs and the infective vector feeds, three things may happen: (*a*) it may lose its infection, either by 'cleansing', due to some immunity process, or through absence of opportunity for re-infection; (*b*) it may become re-infected by its own strain (type 5); (*c*) it may retain a residual infection in its tissues, so that the next stage in that generation is also infective (type 6).

In (*a*) and (*c*) it is to be supposed that the result is not affected by the fate of the infection passed to the host; the invading organism may have been killed 'at the beach-head', may have multiplied to cause an inapparent infection, without high concentration at the infection site, or may have increased rapidly in frank infection. Where the vertebrate host reacts to infection the (*b*) kind of transmission sequence—a modified stage-to-stage type—may be generated: if the vector's meal is sufficiently prolonged, as is sometimes possible with ixodid ticks, or where it can have a series of meals on the same host, as with argasids, fleas or bed-bugs, then re-infection may occur.

(5) *Re-infecting transmission.* In this the infecting stage gets back its own infective strain, possibly made more virulent or otherwise conditioned by its short homoiothermous spell. Such re-infection has also been described as perpetuation of infection. This term is obviously unsuitable where the vector is limited to one meal per life-stage, since it might have to be applied to continuation of infectivity merely through a single ecdysis—nymph to adult—in a case where infection was not hereditary.

With certain organisms, for example *Theileria parva*, this re-infection of the infecting tick is necessary, that is, trans-stadial survival apparently does not occur, but in many instances it will be difficult to determine whether the infectivity of the vector is due to trans-stadial survival or re-infection.

Where re-infection occurs regularly, and there is no hereditary barrier in the vector, then indefinite perpetuation should occur, differing from the vertical transmission of Gross only in that the organism is subjected to a regular alternation of arthropod and vertebrate host. It is tempting to use Andrewes's term 'zig-zag' to distinguish this modified form of vertical transmission sequence, but this would be an unjustifiable restriction of the original intention of the term.

(6) *Trans-stadial transmission.* This means the carrying over of infection, latent or residual, throughout a complete stage, and through two ecdyses. The intermediate stage may be active, as in the case of a three-host tick, where infection acquired by the larva would be transmissible by the female, whether or not the nymph was infective.

It is to be noted that in these definitions the term infection is applied, for convenience, to the stage which takes in the infected meal. A tick larva thus acquires infection in an uncritical sense, but the infective agent may never invade an organized larval tissue, that is, the nymph may well be the first stage to become infected in the strict sense. In trans-stadial transmission, the nymph may or may not be infective. With ticks infected as larvæ with tick-borne fever, for example, the nymphs are infective; if they feed on a non-susceptible host, the female is still infective. In the intermediate stage, however, the infection may be latent, or infectivity may be frustrated as in a pupal stage.

(7) *Transoval transmission.* This is merely a special instance of type 6—trans-stadial transmission—since the egg is the equivalent of a stadium, but it requires to be separately described for two reasons: (*a*) The mechanism of a transoval barrier to propagation of a microbe may be different to that preventing trans-stadial propagation. Trans-stadial survival is possible without hereditary survival, for example in tick-borne fever of sheep. (*b*) Transmission from the adult to the larval stage may not be through the female; infection of the egg may be due to the male. This possibility of male transmission will probably receive more attention in the future than it gets at present, for the possibility of doubling the infection-rate in the larval population is obviously going to be extremely important in those cases where there is only a very low percentage 'take' among adults exposed to infection.

The most commonly used term to-day for hereditary transmission in the vector is 'transovarial'. It is regrettable that this word has crept into general usage, for it is unsatisfactory on two counts: (*a*) it excludes transmission by the male to the zygote; (*b*) although the prefix 'trans' is permissible for an imagined passage across a complete stadium, 'trans-ovarial' merely implies passage across an adult organ. Even conceding that it could be taken to mean penetration into the ovariole, it is still inadequate as it does not necessarily imply entry into the egg or persistence into the larval stage.

There may be objection to the term 'hereditary' because of the implication of a genetic factor. 'Egg-borne', which has also been used, has an undesirable connotation with fomites. Probably the most appropriate word is congenital, but for homology with trans-stadial the term transoval is suggested.

The scrub-mite, which feeds on animals only as a larva, is an interesting case in that transmission by it of the rickettsia of mite typhus must necessarily be both trans-stadial and transoval.

(8) *Interrupted vertical transmission.* Basically from one generation to another in the same lineage of either host, the term, in relation to arthropod-transmitted disease, would imply ability of an organism to survive repetitive trans-stadial/transovval propagation in the vector, as possibly in an arthropod reservoir of a vertebrate pathogen. A break in the series of vertical transmissions might conceivably be due merely to a casual accident, such as eating of the arthropod, and here we are up against the limiting case where it is doubtful if we can justifiably regard the arthropod as vector rather than definitive host. Such vertical transmission obviously must be occasionally interrupted, for us to become aware of it. The next type in the series, unbroken vertical propagation, carries our subject beyond the limits of the field of disease transmission.

I am grateful to Dr. C. H. Andrewes and Dr. C. E. Gordon Smith for their comments on the classification, which have removed some at least of its weaknesses.

PHYSIOLOGY AND PATHOGENESIS OF THE STEIN–LEVENTHAL SYNDROME

By Dr. VIRENDRA B. MAHESH and Dr. ROBERT B. GREENBLATT
Department of Endocrinology, Medical College of Georgia, Augusta

Urinary Androsterone, Etiocholanolone, Pregnanetriol and Δ^5-Pregnenetriol of Ovarian Origin in a Patient with Stein–Leventhal Syndrome

It has been observed by several workers that patients suffering from idiopathic hirsutism and Stein–Leventhal syndrome have elevated levels of urinary androsterone (5α-androstane-3α-ol-17-one) and etiocholanolone (5β-androstane-3α-ol-17-one)[1–4], and that there is a marked decrease in the excretion of these steroids on wedge resection of the ovary[1,3,4]. Cox and Shearman[5] have found normal levels of pregnanetriol (5β-pregnane-3α,17α,20α-triol) and elevated levels of Δ^5-pregnenetriol (Δ^5-pregnene-3β,17α,20α-triol) in patients with Stein–Leventhal syndrome. The role of the adrenals and the ovaries in the secretion of these steroids has been a subject of much discussion in the past. In the present work a complete fractionation and individual estimation of urinary steroids of a typical case of Stein–Leventhal syndrome has been carried out under various medications and the results compared with those of a normal subject, in order to establish the origin of the above-mentioned compounds.

Aliquots of the 24-hr. urine (1/20 volume) were evaporated to near dryness at 45° on a flash evaporator and incubated with 0·5 ml. gluculase (50,000 units β-glucuronidase; 25,000 units phenol sulphatase) in acetic acid–sodium acetate buffer (*p*H 4·8) at 40° for 16–18 hr. After a preliminary extraction, the urine and washings were hydrolysed with hydrochloric acid at *p*H 1 at room temperature for 24 hr. and re-extracted. The extracts were combined, and the separation and estimation of steroids made using the method of Bush and Mahesh[6]. The estimation of pregnanetriol and Δ^5-pregnenetriol was carried out by eluting the appropriate zones from paper, followed by oxidation with periodic acid and assayed as etiocholanolone and dehydroepiandrosterone.

The patient with Stein–Leventhal syndrome was sent to hospital, and two 24-hr. urine samples were collected as controls (Controls 1 and 2). She was then given 25 units of adrenocorticotrophic hormone (ACTH) intravenously for two consecutive days and urines were collected (ACTH 1 and 2). This was followed by 4 days of β-methasone, 0·6 mgm. four times daily, and the urines were collected on the last two days (β-methasone 3 and 4). Finally, 0·3 mgm. of β-methasone four times daily and 5 mgm. of human follicle-stimulating hormone (FSH) once a day were administered concurrently for 6 days, and the urines collected on the last two days (FSH 5 and 6). This was followed by wedge resection of the ovary, and another 24-hr. urine specimen was collected a week after surgery and withdrawal of medications (post-

operative). A similar examination was made of a normal subject with carcinoma *in situ* of the cervix, with the exception that ACTH was not administered to this case. The results of the urinary assays are presented in Table 1.

These results show that the patient with the Stein–Leventhal syndrome had elevated levels of androsterone and etiocholanolone before and after β-methasone suppression as compared with the normal subject. Human FSH brought about an average increase of 8·4 mgm. of androsterone and etiocholanolone in the patient suppressed with β-methasone, whereas the corresponding increase in the normal was 0·5 mgm. Further, there was an almost ten-fold increase in the levels of pregnanetriol and Δ^5-pregnenetriol when the patient was on human FSH. The increase on ACTH administration was only four-fold. The large amounts of androsterone, etiocholanolone, pregnanetriol, and Δ^5-pregnenetriol in the urine, when the patient was stimulated with human FSH, appear to be of ovarian origin. The human FSH administered appeared to be reasonably free of ACTH contaminants as indicated by the absence of urinary tetrahydrocorticosteroids and 11-oxygenated 17-ketosteroids. The ovarian origin of Δ^5-pregnenetriol is further confirmed by the isolation of 17α-hydroxy-Δ^5-pregnenolone in the ovaries of the patient. The ovaries, as well as the peripheral blood, also showed the presence of large amounts of dehydroepiandrosterone when the patient was given human FSH. Furthermore, incubation of ovarian slices from the patient with various steroid precursors indicated a failure of the enzyme 3β-ol dehydrogenase, thus accounting for the presence of large quantities of 17α-hydroxy-Δ^5-pregnenolone and dehydroepiandrosterone in the ovary[3]. The urinary pregnanetriol, androsterone and etiocholanolone may be metabolites of the ovarian 17α-hydroxy-Δ^5-pregnenolone (ref. 7) and dehydroepiandrosterone[8].

Role of FSH in the Pathogenesis of the Stein–Leventhal Syndrome

Hypergonadotrophism has been cited as the basis for the polycystic ovary ever since the report of Stein and Leventhal[9]. McArthur *et al.* have pointed out that luteinizing hormone (LH) assays are persistently though only moderately elevated[10]. The constancy of theca cell hyperplasia has been interpreted as synonymous with theca luteinization and excess LH has been implicated[11]. More recently, Gallagher suggested an adrenal component in the Stein–Leventhal syndrome[2]. Our investigations seem to indicate an inherent enzymic defect in the ovaries leading to hyperovarianism and resulting from persistence of FSH stimulation.

For some time we have suspected that FSH might be a factor in the causation of the large pale polycystic ovaries. Wedge resection has proved beneficial because of reduction of ovarian mass which in all probability permitted a better ratio of endogenous FSH and LH per unit of ovarian tissue. Total urinary gonadotrophins have been shown repeatedly to assay within normal limits, so that the claim of hypergonadotrophism has not been substantiated. The administration of human chorionic gonadotrophin (APL), a substance more closely allied to LTH (luteotrophin) than LH, has not been attended by any real degree of enlargement of the ovaries. In the present work, 5 mgm. of human FSH was administered daily for 6 days to a normal female and to two patients with Stein–Leventhal syndrome. The administration of human FSH induced at least a five-fold enlargement of the ovary in the two patients with Stein–Leventhal syndrome (Fig. 1), but no noteworthy increase in size of the ovary of the patient with normal ovulatory cycles. Keetal *et al.*, employing highly purified sheep FSH, noted markedly responsive ovaries in patients with the Stein–Leventhal syndrome but not in normal women[12]. Furthermore, when APL was administered following FSH to one of the Stein–Leventhal syndrome patients, multiple corpora lutea in various stages of development were induced. The ovaries were not enlarged any further over those of the FSH stimulation as to gross size except for the corpora lutea bulging the surface (Fig. 2). Histologically, FSH alone caused marked follicular growth. The follicles were lined by many layers of granulosa cells and the cells of the theca interna frequently appeared swollen and hyperplastic (Fig. 3). When APL was given following the FSH, corpora lutea in various stages of development were numerous; the granulosa cells were hypertrophied and luteinized comparable to that seen in corpus luteum formation (Fig. 4). In a measure, the effective addition of gonadotrophins to women with unresected polycystic ovaries is comparable with the effectiveness of endogenous gonadotrophins on the wedge resected ovary. In one of our experiments, simply removing one of the polycystic ovaries, leaving the contralateral ovary intact and untouched allowed the same chain of events to occur with induction of cyclic ovulatory menses[13]. Furthermore, the employ-

ment of glucocorticoids in certain patients with Stein–Leventhal syndrome has frequently proved successful[4,14,15]. This finding confounded the confusion as to its etiology and seemed to support the adrenal origin for the syndrome. The similarity in response to wedge resection and corticoid therapy has been noted in several instances and this observation helped to clarify the situation. For example, one recent patient responded satisfactorily to wedge resection by cyclic ovulatory menses and conception. A few years later this patient experienced a recurrence of the syndrome. Dexamethasone therapy was instituted with return of cyclic ovulatory menses and subsequent pregnancy. It may be assumed that glucocorticoids act by permitting release of more gonadotrophins either through suppression of ACTH or some of the adrenal steroids. Sohval and Soffer have shown increased release of gonadotrophins following cortisone therapy[16]. These observations lend support to the concept that whatever improves the ratio of gonadotrophins to ovarian mass, either by exogenous administration of gonadotrophins, wedge resection, removal of one ovary, or glucocorticoid therapy, may prove corrective at least temporarily.

It may be conjectured that the Stein–Leventhal ovary is sensitive and highly responsive to endogenous FSH so that hundreds of follicles receive inadequate stimulation, producing a myriad of microfollicular cysts and a general enlargement of the ovary. The available LH is insufficient to induce ovulation not only because of its dilution per unit of ovarian tissue but also because the maturation of the prime follicles is incomplete. However, when exogenous FSH is administered certain follicles are brought to a further stage of maturation so that when APL is added these follicles are transformed to corpora lutea.

It is probable that the Stein–Leventhal ovary is the result of persistence of endogenous FSH stimulation due to an inherent enzymic defect in the ovary. This view is confirmed by incubation studies with ovarian slices from two patients with the Stein–Leventhal syndrome in whom a failure of the enzyme 3β-ol dehydrogenase was demonstrated[3]. According to the present concept of steroid biosynthesis in the ovary, cholesterol is transformed into œstrogens via Δ^5-pregnenolone, progesterone, 17α-hydroxyprogesterone and Δ^4-androstenedione. In our studies the synthesis of steroids in the Stein–Leventhal ovary did not seem to follow the normal sequence. It appeared that the ovaries, because of enzyme failure, converted Δ^5-pregnenolone to dehydroepiandrosterone via 17α-hydroxyΔ^5-pregnenolone, so that output of ovarian œstrogens is considerably diminished. The lessening of a regulatory influence of the œstrogens on the pituitary permits the persistence of FSH stimulation with the ultimate development of large pale ovaries—the polycystic ovary of the Stein–Leventhal syndrome.

A detailed report of this investigation will be presented elsewhere, for we have found several variants of the Stein–Leventhal syndrome. We are grateful to Dr. Elmer Alpert of Merck, Sharp and Dohme for the supply of human FSH, and to Drs. S. Conrad and W. Hermann for estimation of blood dehydroepiandrosterone sulphate. This work was supported by grant No. *A*–4429 from the National Institute of Arthritis and Metabolic Diseases.

EVALUATION OF QUANTAL NEUTRALIZATION TESTS

By Prof. S. FAZEKAS de ST. GROTH

Department of Microbiology, Australian National University, Canberra

VIRUSES are readily neutralized by specific antibody, and there are several well-tried methods for the assay of antisera. Unfortunately, the slope of dose-response curves varies when different sera are tested in the same host system, or when the same serum is tested in different hosts. Neutralizing titres can be compared, therefore, only by ignoring a basic property of the reaction; if this property, the variability of slopes, is recognized, no comparisons can be made at all. It is a pity that the practical immunologist cannot go about his job both intelligently and with a clear conscience.

The dilemma, however, is not insoluble. It will be shown that by a simple transformation, based on the theory of virus-antibody interactions[1], the quantal dose-response curve becomes linear with unit slope over the practically important range of concentrations. The new metameter defines a natural unit for the comparison of antisera, and also allows the estimation of other constants entering the neutralization process.

Definition of the metameter. The basic equilibrium between antigenic sites on the virus particle and antibody molecules is defined by:

$$K = \frac{[sV(1+n) - x][A - x]}{[x]} \qquad (1)$$

where K is the dissociation constant, s the number of antigenic sites per virus particle, V the concentration of infective and nV the concentration of non-infective particles, A the concentration of antibody molecules, and x the concentration of formed antigen-antibody complexes.

If, as is likely[2], a single molecule of antibody bound to a critical site neutralizes the infectivity of a virus particle, the fraction of survivors will be:

$$\frac{V_s}{V} = \left(1 - \frac{x}{sV(1+n)}\right)^c \qquad (2)$$

where V_s is the concentration of surviving infective particles, and c the number of critical sites per virus particle. In a quantal test V_s is unity, by definition. Here equation 2, solved for x and written now in logarithmic form, will read:

$$\log V = -c \log\left(1 - \frac{A}{sV(1+n) + A + K}\right) \qquad (3)$$

At low virus input the value of $sV(1+n)$ will be smaller than K by several orders of magnitude, and can therefore be safely neglected. This leads to:

$$\log V = c \log(1 + A/K), \text{ if } sV(1+n) \ll K \qquad (4)$$

The term $\log(1 + A/K)$ may be expanded to give:

$$\left[\frac{A}{K} - \frac{1}{2}\left(\frac{A}{K}\right)^2 + \frac{1}{3}\left(\frac{A}{K}\right)^3 - \ldots\right] \log e$$

Since in this region A/K is at least two orders of magnitude lower than unity, its higher powers are completely negligible in any biological argument. Thus we may write, with good approximation, by using the first term only of the rapidly converging series:

$$\log V = c\frac{A}{K} \log e \qquad (5)$$

for equation 4. It is evident that equation 5 can now be turned into a linear function of A, with unit slope, by taking logarithms of both sides:

$$\log\log V = \log A + \{\log c - \log K - 0{\cdot}362\} \qquad (6)$$

This, the loglog plot of quantal neutralization tests, is seen to be linear over the range defined above, with a slope of unity.

To demonstrate that the approximations incorporated in equation 6 are fully justified, a family of theoretical neutralization curves[3] will be re-plotted on the new scale.

Such theoretical curves have been obtained by programming a digital computer to solve equation 2 for a wide range of the parameters V, A, K, s, c, n. Representative sets of these curves were plotted on a ($\log A$, $\log\log V$) scale. The empirical choice of this scale is due to Dr. K. J. Lafferty; it was the then unaccountable discrepancy of $-0{\cdot}36$ which prompted closer examination of the equations and led to the present treatment. It was evident that for all values of K, s, c, and $(1 + n)$ likely to occur in practice the loglog plot is linear from $V = 1$ to at least 10^4, and usually beyond 10^6. This covers most of the doses used in routine neutralization tests.

The unit of neutralization. The effect which altered the slope of orthodox ($\log A$, $\log V$) curves—the bracketed term of equation 6—is here seen to govern the intercept of the dose-response line with the abscissa. This intercept commends itself as the natural unit of potency by which antisera may be compared. It corresponds to that concentration of antibody which allows one out of ten infective units to remain free. It should be noted that this value, which may be called the neutralizing dose, is a compound of the quantity (that is, $\log A$) and the quality (that is, $\log c - \log K$) of antibody; the numerical constant, $-0{\cdot}362$, arises from using common rather than natural logarithms, and equals $\log\log e$.

The neutralizing dose is a practical unit: it measures the potency of antisera as they function in laboratory tests and, indeed, in Nature. It is common knowledge that the infective dose by which diseases are transmitted under field conditions lies in the range of 1–10^4 ID_{50}, and it has been shown above that these values fall on the straight limb of the loglog plot. A further practical advantage is that in this range the neutralizing dose is independent of $(1 + n)$, that is, of the ratio of infective to non-infective particles. The importance of this aspect will be appreciated fully on reflecting that the $(1 + n)$ term varies widely from one host system to another, and from one virus preparation to another; its value under field conditions is not readily amenable to measurement, and usually unknown. Differences in test volume, shown to have a profound effect on both the shape of the dose-response curve and the end-points obtained[4], have a simple additive effect on the loglog plot: if the test volume is not unity (1 cm.^{3}), its actual volume will appear in the bracketed term of equation 6, giving $\{\log c - \log K - \log v - 0{\cdot}362\}$, where v stands for the test volume in cm.^{3}. It is obvious that by this method results obtained in one system should be directly comparable with results obtained in any other quantal neutralization test.

The concept of the neutralizing dose may be taken one step further. If an antiserum is found to contain one neutralizing dose when diluted $10 - d$, its potency may be expressed as the negative logarithm, d, of this dilution. So defined, the *neutralizing potency* or *pN* is a form of notation entirely analogous to *p*H. The analogy holds even to the extent that *p*H is a compound of the concentration and activity of dissociable hydrogen atoms. But while the activity there can be defined by a single equilibrium constant, in the more complex system of virus and antibody it involves the bracketed term of equation 6, even over the linear part of the loglog plot. Based on this analogy, we shall talk about neutralizing activity of a particular serum when referring to the quantity $\{\log c - \log K - 0{\cdot}362\}$. Clearly, this value can be read off the loglog plot as $(\text{loglog } V - \log A)$, provided the concentration of antibody molecules has been determined by some independent method, as shown elsewhere[5].

Calculation of *pN*, the Neutralizing Potency

Conventionally, viruses are reckoned in median infective doses (ID_{50}), and not in infective units. In a system where susceptibility does not vary from host to host, one ID_{50} equals 0·693 infective unit. As both the concentration of antibody and the number of ID_{50} are usually expressed in $\log_{10}$ units, the neutralizing potency of a serum can be calculated very simply: the logarithm of the neutralizing titre ($\log V$) minus 0·16 (that is, log 0·693) is subtracted from the final concentration of serum. The actual procedure will be made clearer by applying the method to the first assay from our paper on the neutralization of influenza viruses[4].

An antiserum, diluted in two-fold steps, was mixed with five-fold dilutions of the homologous virus in all possible combinations, using ten replicates at each level. The observed infectivity end-points, worked out by the method of cumulative totals, are given in the first row of Table 1. By subtracting these from the control (titre of virus in the absence of serum), one obtains the number of ID_{50} neutralized (row 2); taking away 0·16 leaves the number of infective units neutralized (row 3). All these operations were in $\log_{10}$ units, that is, in 'tubes' of dilution. Now the

Comparison of orthodox and loglog plots of data from quantal neutralization tests. *A*, tests of the same virus–antibody mixtures in five host systems (*A* = allantois; *C* = chorion; *L* = mouse lung; *B* = mouse brain; *S* = surviving chorio-allantois). Data of Tyrrell and Horsfall (ref. 6). *B*, tests on the same virus–antibody mixtures in three test volumes (0·35 ml., 1·05 ml., 2·10 ml.) (ref. 3). The ratio of the volumes is shown on the curves. *C*, tests of an antiserum against the homologous and two heterologous antigens (hyperimmune rabbit serum against *SW*-virus; *S* = *SW*-virus; *P* = *PR*8-virus; *M* = *MEL*-virus) (ref. 3)

last value is transformed to loglog *V* by taking its logarithm; a slide-rule will give the required accuracy. The figures obtained (row 4) are subtracted from the serum concentration (head of Table 1) to give row 5, and finally the log of the test volume is added (log 0·30 = – 0·52), giving the neutralizing dose, *ND*. If, as in the example, several estimates are available, we may average them and say that $10^{-4\cdot35}$ ml. of the serum contains one *ND*. The neutralizing potency of the serum will be, of course, $pN = 4\cdot35$.

The average error of such estimates has been determined under a variety of conditions previously[4]; if replicate assays are performed, the error can be determined from the internal evidence of the test. In this example it comes to ± 0·025, in terms of *pN*.

The steps leading to *ND* or *pN* of a serum are set out in detail for purposes of demonstration; they involve four simple subtractions and the looking up of a logarithm to two mantissal places. Obviously, the former can be done by mental arithmetic, and the whole computation takes less than a minute.

Finally, it may be demonstrated, on examples from the literature, that the factors which fundamentally influence the shape and position of orthodox neutralization curves still give a linear loglog plot with unit slope, and lead to a single *ND* or *pN* value for each serum.

Fig. 2*A* shows the data of Tyrrell and Horsfall[6] obtained by testing the same virus-antibody mixture in five host systems. The orthodox plots are incommensurable; the loglog plot leads to the unique *pN* value of 4·70. Figs. 2*B* and 2*C* are our results[3], the former showing the dilution effect, the latter the behaviour of an antiserum when tested against various antigens. Whereas changes of test volume do not influence the loglog plot, the difference of equilibrium constants for the homologous and heterologous systems shows up clearly in their respective *pN* values of 4·68, 3·57 and 2·62.

The aspect to be stressed is the linearity of the loglog plot over almost the whole range of virus concentrations used in practical tests. The variation due to changes in other parameters shows up only in the top part of the curves and, as will be shown later, can be used for the definition of these in the same way as the behaviour of orthodox (log *A*, log *V*) plots has already been used[3,5].

INDUCTION OF TUMOURS BY POLYOMA VIRUS: ENHANCEMENT BY CHEMICAL AGENTS

By K. E. K. ROWSON, F. J. C. ROE, J. K. BALL and Dr. M. H. SALAMAN

Cancer Research Department, London Hospital Medical College, London, E.1

It has been shown that in certain cases viruses and chemical carcinogens may interact so that tumour production is modified. For example, Rous *et al.*[1,2] found that when Shope papilloma virus was injected intravenously into rabbits the ears of which had been painted with tar for 1·5–3 months, many warts and several metastasizing epitheliomata soon arose on the tarred ears. Tarring alone gave rise to a few warts, and only one malignant tumour among ninety rabbits, while the intravenous injection of Shope virus alone was ineffective. Ahlström and Andrewes[3] injected tar or carcinogenic hydrocarbons intramuscularly or subcutaneously into rabbits, and Shope fibroma virus intradermally. In some rabbits the tumours due to the virus grew progressively, in others they slowly regressed. In controls which received the virus alone, rapid regression was the rule. Duran-Reynals[4] found that the intradermal injection of vaccinia virus into cortisone-treated mice produced much more severe local lesions than in untreated mice. These more severe lesions were followed by scar formation. If mice were given a course of paintings with methylcholanthrene on both flanks, before treatment with cortisone and vaccination, benign and malignant tumours developed at the site of the vaccination scar. No tumours were seen in control animals which received no previous treatment with methylcholanthrene or no cortisone at the time of vaccination.

In the present work the interaction of polyoma virus, injected into new-born mice, and two chemical carcinogens, 9 : 10 - dimethyl - 1,2 - benzanthracene (DMBA) and 3,4-benzpyrene (BP), and a tumour-promoting substance, croton oil, applied to the skin of the injected mice, has been examined. The experiments were designed to show, first, whether treatment with a chemical carcinogen or a tumour-promoter can modify tumour induction by polyoma virus, and secondly, whether polyoma infection modifies tumour induction by chemicals; for example, whether it can play any part in the two-stage mechanism of carcinogenesis, as tumour-initiator or promoter, or alter the incidence of malignancy. The second question has an important practical bearing, since polyoma is widespread as a latent infection in mouse stocks[5] such as are used for the testing of chemical substances for carcinogenicity. By injecting the virus into new-born animals, and choosing the dorsal skin as the site for later application of the chemical agents, it was reasonable to expect that answers to both these questions could be obtained at the same time. Chemical carcinogens applied to the skin give rise mainly to skin tumours; mammary, ovarian, and pulmonary tumours, subcutaneous sarcomas, and leukæmia may also be induced, but much less frequently. Polyoma virus, on the other hand, induces tumours of the parotid and mammary glands, renal pelvis, bone, and subcutaneous tissues, and less frequently at a variety of other distinctive sites[6,7]. No superficial tumours of the epidermis have been reported, though one strain has been found to produce enormously hypertrophied hair follicles[6]. When distribution and relative frequency are taken into account there should be little difficulty in distinguishing the characteristic effects of each type of agent.

In order to produce tumours in mice with polyoma virus it is necessary to introduce it either before birth, or during the early neonatal period, into mice from a polyoma-free stock. Mice exposed to the virus after the end of the neonatal period develop antibodies to it, but no tumours. These antibodies may pass to fœtal mice through the placenta, or to new-born mice in the milk, and so provide passive immunity[8]. The mothers of the mice used in the present experiment were all free from polyoma hæmagglutination-inhibiting antibodies. They were divided randomly into two main groups which were thereafter housed in separate rooms under otherwise identical conditions. Both groups were fed diet 41*B* supplemented with rolled oats twice weekly, and provided with water *ad libitum*. All the litters from one group were injected subcutaneously during the first 24 hr. of life with 0·02 ml. of fluid containing 10^6 infective doses of polyoma virus (determined by the antibody production test[9]). The strain of virus used, LHP_1, was originally isolated in this department from a C_3H mouse[10] and the material used for injection in the present experiment was the tissue culture fluid and homogenized cells from the fourth mouse embryo tissue culture passage. The group of mice injected with polyoma virus was designated '$P+$' and the control group 'P-free'. The latter litters were injected while less than 24 hr. old with culture fluid from the fourth passage of uninfected mouse embryo tissue. 9,10-Dimethyl-1,2-benzanthracene (DMBA) and 3,4-benzpyrene (BP) were obtained from L. Light and Co.; croton oil from Stafford Allen and Co.; and acetone ('Analar' grade) from British Drug Houses, Ltd.

In general the $P+$ mice grew less well than the P-free mice. Several of the former showed abnormalities of hair growth in the form of bald patches and a sticky appearance of the hair. However, from the tenth week onwards these symptoms disappeared and the mice grew progressively to the same size as the P-free controls. It is most unlikely that the early effects on growth and on the skin were due to the polyoma virus. We were able to isolate a virus in tissue culture from the tissues of similarly affected mice which when injected into mice 5–7 days old reproduced the condition, but was lethal to new-born mice. A similar syndrome has been described by Stanley *et al.*[11]. The inoculum used in the present experiment was found to be free of this agent, which was clearly distinguishable from polyoma virus by the type and species specificity of its cytopathogenic effect in tissue culture. It would seem that the $P+$ groups became accidentally infected with this virus, whereas the P-free groups, housed in another room, remained free of it. All the mice were weaned and sexed at four weeks of age. Ten experimental groups were then constructed, five consisting of $P+$ mice and five of P-free mice. Each group consisted of sixteen males and sixteen females, and mice from individual litters were distributed as widely as possible among the five groups for which they were eligible. By using an ear-punch system of numbering it was possible throughout the experiment to determine from which litter a mouse was derived.

The ten groups were treated with chemical agents (Table 1) and have now been observed for six months. Taking the results in the four groups treated with chemical substances (groups 2–5) together, they had a higher incidence of polyoma tumours than the control unpainted group (group 1). This difference was significant according to the χ^2 test ($0{\cdot}01 > P > 0{\cdot}001$). With regard to epidermal tumours attributed to the treatment with chemical agents, apart from one papilloma in group 9 (P-free and croton oil only), they were only seen in the groups treated with DMBA + croton oil (groups 3 and 8), or with BP twice weekly (groups 5 and 10). The injection of polyoma virus into new-born mice had no marked influence on their subsequent response to treatment with DMBA + croton oil; papillomas began to appear after the sixth week of croton oil treatment in both groups, approximately the same proportion of mice developed papillomas, and the total numbers of tumours after fifteen weeks of croton oil treatment, though on an average somewhat greater in the $P+$ than P-free mice (6·4 and 4·4 per survivor, respectively), was not regarded as significantly different. However, in the group which received weekly BP-treatment a definite difference in response was seen: tumours began to appear during the thirteenth week in the $P+$ mice (group 5) and not until the seventeenth week in the P-free (group 10). At the present time (twenty-first week of treatment with BP) there are forty-eight benign and six malignant tumours in twenty-three $P+$ survivors, but only fourteen benign and one malignant tumour in thirty P-free survivors. Treatment and observation of these two groups continue. In addition to the tumours which could without

‡ Parotid gland tumours were multicentric in origin. Involvement of one gland counted as one tumour, and both glands as two tumours.

§ Including bone, mammary glands, and subcutaneous tissues.

doubt be attributed to the polyoma virus, or to treatment with chemical agents, there were seen, in the groups 1–5, a number of cystic lesions in the subcutaneous tissues. Several of these appeared to be simple lymph-filled cysts arising in lymph glands, others were multilocular or filled with thin blood-stained fluid, and not obviously associated with a lymph gland. None of them had any solid elements, and it is doubtful whether any of them were neoplastic. The incidence of mice with these lesions in groups 1–5 was 4, 3, 2, 5, and 4 respectively.

At this point it is necessary to consider a factor which slightly complicated the experiment. During the ninth week of treatment with chemical agents, eight males and eight females from each of the five experimental groups of *P*-free mice (groups 6–10) were tested for hæmagglutination-inhibiting antibodies. All tests were negative. At this time there were already several benign papillomas in group 8. Nine weeks later, a second check for antibodies was made, and on this occasion several positives were found (0/32 in group 6, 1/29 in group 7, 9/30 in group 8, 10/30 in group 9, and 4/30 in group 10). Clearly the polyoma virus had found its way into the *P*-free colony and the infection had begun to spread. However, by this time, except in the case of groups 5–10, the experiment was over, and this incidence of mice with antibodies in the *P*-free group was not sufficient to invalidate conclusions which could otherwise be drawn. In point of fact there was no association between the number of tumours and the presence of antibodies in individual mice of group 8.

The number of tumours which developed in the group of mice which were infected with polyoma virus when newly born, but received no other treatment, was less than was expected from previous experience of this strain of virus. It is possible that an accidental secondary viral infection, which has been described, had an interfering action. However, since all the polyoma-injected mice suffered from this infection, the difference in polyoma-type tumour incidence between the groups which received subsequent chemical treatment and the group which did not is not invalidated. It is conceivable that the difference in the incidence of skin tumours between *P*+ and *P*-free mice treated with chemicals may have been due in part to both viruses, but very unlikely that the accidental infection both inhibited tumour-induction by polyoma virus and enhanced the effect of chemicals on it. Despite the complicating factors the following conclusions appear justified: (1) Mice inoculated with polyoma virus when newly born and later treated by application to the skin of carcinogenic or tumour-promoting agents developed significantly more polyoma-type tumours than mice which received the virus alone. (2) Skin tumours which developed in mice treated repeatedly with BP appeared sooner and in larger numbers, and more became malignant, in those which had been injected when new-born with polyoma virus than in those which had not. (3) Injection of polyoma virus into new-born mice did not initiate tumour formation, as shown by the failure of subsequent treatment with croton oil to produce skin tumours. (4) Polyoma virus injected into the newly born mouse is known to persist throughout life. The presence of this virus did not promote the formation of tumours in mice given an initiating application of DMBA at 7 weeks of age. (5) An intercurrent infection which produced symptoms in all polyoma-injected mice is described. Reasons are given for the view that these conclusions are not invalidated by this accident.

We gratefully acknowledge the technical assistance of Miss C. de Mengel. The cost of this research was in part defrayed out of a block grant from the British Empire Cancer Campaign.

SPACE SCIENCE

Analysis of Satellite Data

Using the method outlined in previous papers[1-3], I have completed an analysis of an extensive series of observations on satellite 1958 δ2 (ref. 4), and propose to outline an interesting implication of this work prior to the publication of the detailed analysis.

The method of analysis makes use of the near linearity of v^2 as a function of t, where $v = ae/a_0e_0$ in standard orbital notation. Fig. 1 shows the departure (δ) of v^2 from linearity after the removal of the important oblateness terms. The curve is composed effectively of three distinct nearly linear sections, *AB*, *BE*, *EF*, the change of type being unrelated to solar or any other obvious effects. However, the analysis is based upon the constancy of the scale height H, and for any linear section:

$$\delta = 1 - Kt$$

where[3] $\rho\sqrt{H}/f(v) \approx K$. The mean value of H is determined by the behaviour of the perigee distance[3], a least-squares fit giving the value 46·0 km. for this satellite, and the mean value of K is $1 \cdot 468 \times 10^{-3}$. If then we compare the gradient of a linear section with the mean gradient we can form an estimate of the local value of H. Since the v^2-trace does not depart from the mean trace by more than 2 per cent we can ignore the variation of $f(v)$ in the comparison. If ρ is greater than its implied mean value then the effect of ignoring the variation of ρ is to over-estimate the corresponding value of H and conversely.

An examination of Fig. 1 shows that the gradient changes very sharply at B and E, in fact almost discontinuously, the changes being unrelated to changes from day to night. If the main part of the gradient change is due to variations in H this would imply a step-like temperature distribution and consequently a considerable degree of stratification. The section *CD* is anomalous in its behaviour, showing a day–night variation in gradient more than three times as large as that of the neighbouring regions. The single oscillation apparent is fitted almost exactly by a multiple of sinψ, where ψ is the difference in longitude between the perigee and the sub-solar point. This implies a maximum of $\rho\sqrt{H}$ at midday and a minimum at midnight, the magnitude being independent of altitude in this limited region. A daytime rise in density due to the lifting of warmed air would be expected to produce a uniform variation of gradient over a limited region, hence it is reasonable to attribute the major part of the oscillation over *CD* to variation in scale height. In Fig. 2 scale heights calculated in this manner are compared with King-Hele's[5] estimates of H, modified to give true scale heights. The agreement is fair, sufficient to justify the general interpretation, though the implied temperature peak is much sharper than King-Hele's necessarily smoothed values. The excessively low values below 190 km. are probably the result of a progressive fall-off in solar activity at this time, which has not been taken into account.

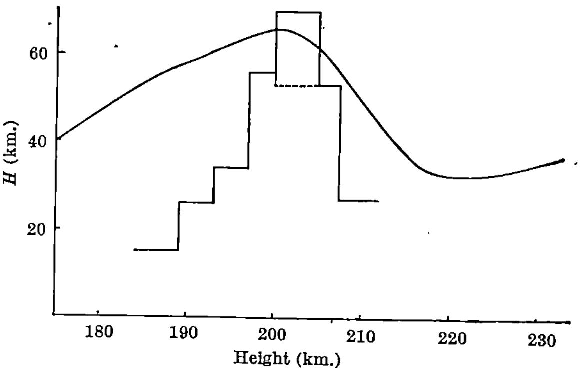

Fig. 2. Graph of scale height, comparing values deduced from K-variation with estimates from density values

The anomalous behaviour between 200 km. and 205 km., which is most probably the result of a marked day–night temperature difference, suggests strongly that this is the region of high absorption of solar energy which is the cause of the F_1-layer. Whatever interpretation is finally accepted for this anomalous behaviour, its relation to the F_1-layer is difficult to avoid. For example, if its explanation is sought in a marked variation in charge drag, one is faced with a high concentration of charged particles in a region of limited depth.

When this analysis was begun, one of my main aims was to obtain further justification for my earlier interpretation of oscillations in the v^2-trace for 1958 δ1 as a third harmonic tide. In Fig. 3 the remaining variations in v^2 after the removal of known effects are shown and compared with the calculated effects of a third harmonic tide. Solar flux variations do not account for these oscillations, which happen to coincide with a particularly quiet solar period, and furthermore, the oscillations occur at approximately the same level as those observed in the data for 1958 δ1. The disturbance is restricted

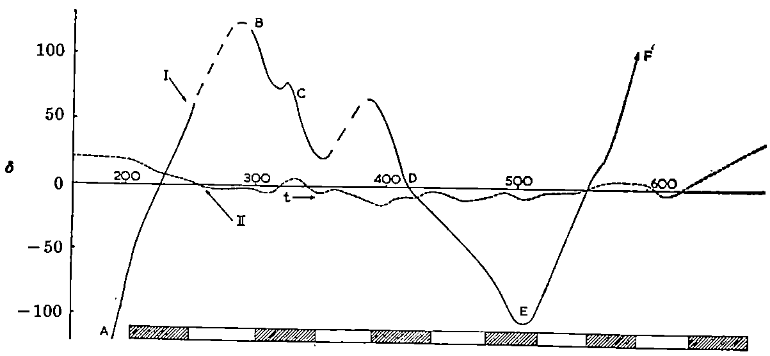

Fig. 1. Graph of δ vs. t for 1958 δ2 with the oblateness effect removed. Curve I, δ × 10⁴; Curve II, effect of variation of solar flux estimated from relative sunspot numbers. Time t in y.d. 1958. Shaded sections denote daytime (| ψ | < 90°)

to the section *BE* of the trace and is therefore limited to a depth of about 10 km. Since the earlier set of data for 1958 δ1 was of short duration, it is impossible to say whether or not the oscillations were restricted to the temperature peak, but a sharp rise in v^2 after the values given in Fig. 1 of my earlier communication[2] would suggest that the oscillations recorded there belong to the section *DE*. It is evident that a slight change of phase with height occurs, but it would be surprising if a tidal phenomenon did not show this effect. Although classical tidal theory is scarcely applicable to these regions and my earlier estimates of temperature were in error, there are strong indications that if a third harmonic tide occurs it must occur in a relatively thin shell near the 200-km. level. There has been some criticism of the suggestion of tides at this level[6–8], but in the face of this evidence the interpretation must surely be considered justified. This tidal oscillation is of small amplitude and is not particularly important in the general density pattern, but its implications for the dynamical structure of the atmosphere are worthy of consideration.

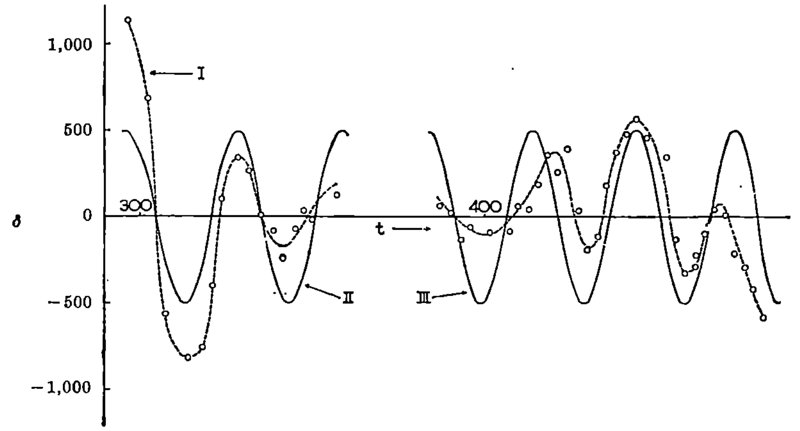

Fig. 3. Graph of δ vs. *t* for section *BE*. Curve I, $\delta \times 10^6$; Curve II, $\cos (3\psi + \pi/4)$: Curve III, $\cos 3\psi$. Time *t* in y.d. 1958.

It must be emphasized that the effects considered here are long-term, in contrast to the violent day-to-day fluctuations observed in the rate of change of periodic time. Since the v^2-analysis uses the periodic time rather than its rate of change, the effect of integrating density variations is to enhance the slower oscillations. As a result it is found that solar flux variations are scarcely noticeable in the resulting traces, although such variations are closely correlated with the daily variations of the orbital acceleration.

I wish to thank the South African Mutual Life Assurance Society for the use of its computer for the early stages of the numerical analysis.

PHYSICS

Spatial Distribution of Free Radicals as studied by Electron Spin Resonance

The spatial distribution of free radicals produced by irradiation is of interest in radiation chemistry and radiation biology. Although there have been many theoretical treatments of this problem, direct experimental evidence has so far been lacking. Electron spin resonance spectroscopy provides a means of measuring the distribution of free radicals; and we report here a preliminary investigation by this method.

The technique depends on the phenomenon of dipolar broadening, in which the width of the electron spin resonance absorption line is increased by the perturbing effect of neighbouring free radicals. Since the perturbing effect varies inversely with the cube of the distance between two radicals, the broadening is a measure of the local concentration and not of the overall concentration, for cases where these differ owing to a non-uniform distribution.

Kittel and Abrahams[1] have calculated the broadening due to a uniform random distribution of magnetic centres in a single crystal. They showed that for moderate concentrations the line shape is approximately Lorentzian; and they gave a numerical formula for the line width. This may be written in the convenient form $B = 68\ M$ gauss, for $M \leqslant 1$, where M is the molar concentration of free radicals, and B is the increased separation, due to dipolar broadening, between the points of inflexion. The formula can be used for powders, glasses or liquids, with a different numerical value of the constant; and also for a non-uniform distribution of radicals, provided that M now represents the local concentration of radicals.

We have applied this technique to glasses of H_2O_2 in H_2O and of D_2O_2 in D_2O, irradiated and measured at 90° K.[2,3]. The spectra are complicated by *g*-value anisotropy and by hyperfine splitting; but in many cases we have been able to fit the experimental line shape to one calculated[4–6], and thus obtain the line width. As a preliminary check we used very large doses of radiation (up to 10^8 rads, giving concentrations of radicals up to 0·5 M) in order to obtain a uniform distribution of radicals. As the dose increased the line shape changed from Gaussian to Lorentzian, in accordance with the calculations of Kittel and Abrahams[1]; and the increase in separation between the points of inflexion was measured as $35 \pm 18\ M$ gauss. The line shape with no dipolar broadening was obtained by softening the glass at a temperature of about 140° K. until there was no further change in shape. This process produces a low concentration of radicals distributed uniformly. (The change in line shape as the glass softens was incorrectly attributed in an earlier communication to the production of a second radical[2].)

We then observed that different types of radiation produced spectra with different line widths, greater

Table 1. Local Concentration of Radicals

15 MeV. deuterons	14	(0·08 *M*)	(27 Å.)
5·7 MeV. α-particles	86	0·22 *M*	20 Å.
2537 Å. ultra-violet	—	0·33 *M*	—
3100–3500 Å. ultra-violet	—	0·45 *M*	—

The values given in parentheses are near the limit of measurement, and are consequently very approximate.
The values in column 3 are the uniform random distributions which give the same line width.
The values in column 4 are obtained from the formula: average separation = $(6\cdot02 \times 10^{20} M)^{-1/3}$ cm.

than for the spectrum with no dipolar broadening. These line widths were independent of dose, provided that the dose did not exceed a certain value. Furthermore, the principal *g*-values and hyperfine splittings, when present, were the same in every case, indicating that the same radical was always produced. Hence any broadening observed must be due to the local concentration of radicals. The local concentrations obtained in this way are given in Table 1.

With ultra-violet irradiation the primary act must be the splitting of an H_2O_2 molecule into two OH radicals. The radical observed by electron spin resonance has not been positively identified, but it is unlikely to be OH. The ultra-violet observations of Table 1 show that the two radicals observed, or their precursors, diffuse a few Å. apart before being stabilized. A naïve calculation shows that the two OH radicals, when first formed, have sufficient energy to raise the temperature of a sphere of radius 20 Å. (rather more for 2537 Å., rather less for 3300 Å.) to a temperature at which the radicals have been observed to diffuse very rapidly. It is likely that local softening of the glass takes place with ionizing radiation also, so that the initial concentrations of radicals would be higher than those given in Table 1.

Magnetic Relaxation in Magnetite and in its Solid Solutions with Manganese and Nickel Ferrites

Our previous investigation of magnetic relaxation in $(Ni,Zn)_xFe_{3-x}O_{4+y}$ and $(Mn,Zn)_xFe_{3-x}O_{4+y}$ solid solutions with magnetite ($0\cdot85 \leqslant x \leqslant 1$) showed certain similarities to exist among the phenomena which occur in both systems[1]. Such similarities have since been reported by other authors[2,3].

In NiZn and MnZn ferrites the magnetic diffusion occurs owing to the presence of Fe^{2+} cations, by means of vacancy migration. A few distinct relaxations appeared in separate temperature-ranges, with activation energies still of about 1 eV. or 2 eV. (The application of the method of Rathenau[4] has given values of about 0·5 eV. and 1 eV. respectively. This method is not applicable to ferrites having a broad band of relaxation-time constants.) It was feasible to assume that the presence of magnetite or, more exactly, of the $Fe^{2+} - Fe^{3+}$ configurations is essential here.

We then began investigating relaxation in the systems $Mn_xFe_{3-x}O_{4+y}$ and $Ni_xFe_{3-x}O_{4+y}$ by means of permeability disaccommodation measurements, beginning with the particular case of magnetite, $x = 0, y \gg 0$.

The disaccommodation measurements were made on polycrystalline samples in the temperature-range between liquid hydrogen and corresponding Curie points using the Maxwell–Wien bridge. The intensity of the measuring alternating field was 10 m.oersteds, its frequency 1 kc./s. The magnetic permeability was measured as a function of time. Disaccommodation equals $\mu_0 - \mu_{30}/\mu_0$, where μ_0 denotes the value found 1 sec. after demagnetization, and μ_{30} after 30 min.

In a typical disaccommodation spectrum of magnetite $Fe_3O_{4+\gamma}$ we have observed three vacancy diffusion peaks: I, II, III (Fig. 1). The activation energies found are: $W_I = 1\cdot7 \pm 0\cdot3$ eV. (extrapolated from W_I values determined for $x > 0$, intensity of peak I being too small in samples, $x = 0$, $y \gg 0$), $W_{II} = 0\cdot85 \pm 0.10$ eV., $W_{III} = 0\cdot85 \pm 0\cdot10$ eV. In order to determine values of W, we have approximated the $\mu(t)$ curve with the after-effect function[5] $\psi(t)$.

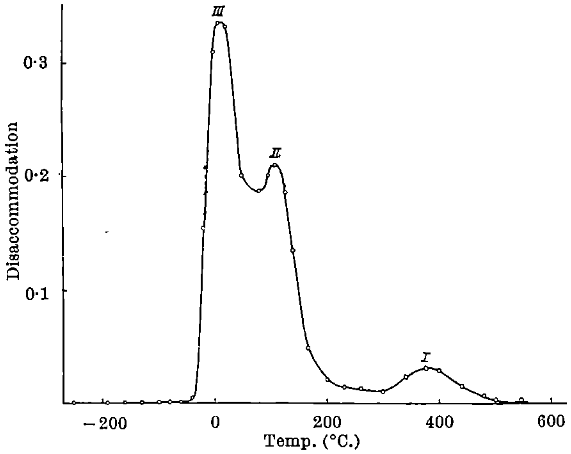

Fig. 1. A typical disaccommodation spectrum of magnetite Fe_3O_{4+y}. $y > 0$

A suitable concentration of vacancies is a necessary condition for the presence of each peak. The $y_{min.}$ value increases progressively for lower temperature effects: for III $y_{min.}$ is greater than for II, etc. For increasing values of $y > y_{min.}$ the peak I is markedly displaced to lower temperatures; the displacements of II and II are much smaller.

In both of the manganese- and nickel-ferrite systems mentioned above one finds the peaks I, II, III for almost all compositions $0 < x < 1$. As x approaches unity, the effect III is the first to disappear, then II, and finally, for the largest values of x, effect I.

The temperatures of peaks I, II, III are almost independent of x for the nickel-ferrite system. This is also true for peaks I and III in manganese ferrite – magnetite solid solutions. One observes, however, a shift of peak II from about 100° C. to approximately 200° C. for compositions $0 \cdot 5 < x < 0 \cdot 85$, having positive cubic anisotropy constant K_1 (ref. 6). Manganese ferrites show also a small peak IV at approximately – 70° C., indicating the contribution of manganese ions to the diffusion process.

For increasing values of y the displacement of peaks occurred in both systems as it did in the case of magnetite.

We therefore believe that in solid solutions of magnetite with other cubic ferrites local configurations of anisotropic space charge ($Fe^{2+} - Fe^{3+}$) are formed owing to the presence of vacancies in octahedral sites having trigonal symmetry. The configurations re-arrange themselves by migration of vacancies when the direction of magnetization changes in magnetic domains from one to the other [111] or [100] axis under the action of alternating demagnetizing fields. Relaxation I corresponds probably to the migration of a few individual vacancies or, equivalently, very limited space charge. The effects II and III might be due to the formation of more complicated arrangements, for example, pairs.

More detailed results and discussions will be published shortly.

Surface Waves in Anisotropic Elastic Media

The possibility of elastic waves confined to the neighbourhood of the free plane surface of semi-infinite isotropic medium was first deduced by Lord Rayleigh in 1885. He found that the amplitudes of such waves decay exponentially with the distance from the surface. Recently there has been interest in the propagation of surface waves in anisotropic media, and Stoneley, Gold, and Deresiewicz and Mindlin have discussed the propagation of surface waves in particular directions and special planes of certain crystalline substances[1].

The general case has been considered by Synge[2]. He expressed the condition for surface wave propagation in a given plane in terms of a complex valued determinant, and deduced that surface waves are propagated only in those isolated directions for which the real and imaginary parts of this determinant both vanish. He also showed that, in general, the variation of the amplitudes of surface waves with depth is sinusoidal as well as exponentially decaying.

More recently[3] it has been shown that if the free surface is normal to the monoclinic axis of a crystal (or equivalently it is a plane of reflexional symmetry), then the determinant is real and, therefore, Rayleigh waves may be possible in any direction. Even for these special planes, however, the wave amplitudes may vary harmonically as well as decay exponentially with depth. Further, using a Fourier transform method, similar to that used in the case of body wave propagation[4], it has been shown[6] that the geometry of the surface waves can be described by 'slowness' and 'wave' curves, where the terminology is similar to that now commonly used in the three-dimensional case[5]. The wave curve represents the positions at unit time of waves which were initially at the origin; it is the polar reciprocal of the slowness curve with respect to the unit circle. Solutions of the determinantal equation give points on the slowness curve; the corresponding points on the wave curve can then be calculated. It is most important that the wave curve should be obtained as, physically, it describes the energy flow.

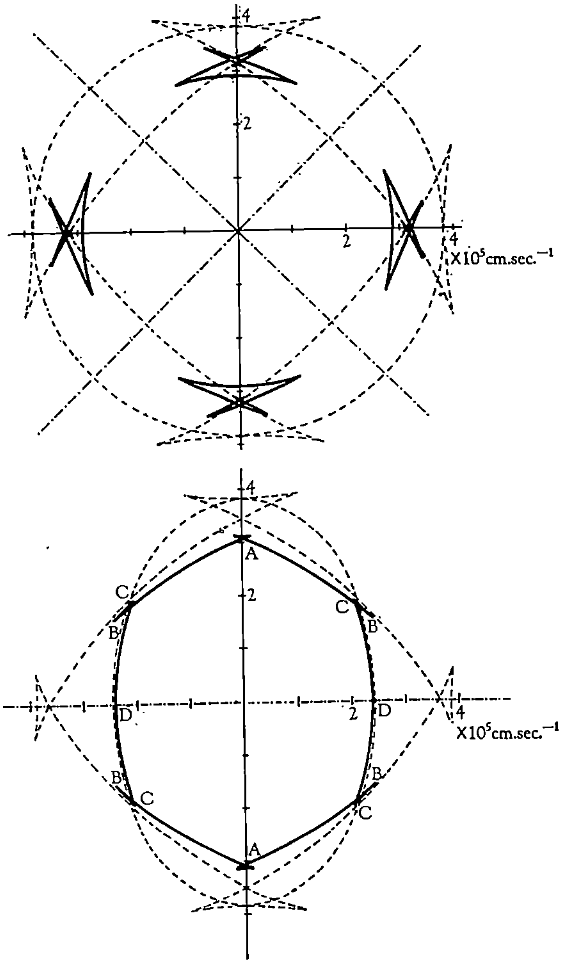

Fig. 1. Above, surface wave curves of iron in the (1,0,0) plane, and, below, similar curves for the (1,1,0) plane. In both figures the fourfold axes are represented by ——, the twofold axes by —·—·—, the surface wave curves by ——, and the curves – – – – represent the intersections of the body-wave surfaces with the appropriate plane. Below, the segments *CBABC* represent waves, where the amplitude variations with depth contain sinusoidal factors, while the waves corresponding to the remaining segments *CDC* have only purely exponential decay

The determinantal equation is too complicated for a closed solution to be practicable. Numerical solutions have been obtained for transversely isotropic materials[6], and graphs given of the slowness and wave curves for apatite, beryl, cobalt and zinc, in the case where the axis of rotational symmetry is parallel to the free surface. Since then a programme has been written for the University of Manchester *Mercury* computer, which produces the relevant information for all classes of monoclinic crystals. For example, in the two figures the full lines are the wave curves for the (100) and (110) planes of iron (the broken lines are the intersections with these planes of the 'transverse' sheets of the body wave surfaces). The stiffnesses used were $C_{11} = 23{\cdot}30$, $C_{12} = 13{\cdot}92$, $C_{44} = 11{\cdot}62$ in 10^{11} dynes/cm.^{2}, the density being 7·87 gm./cm.^{3} (ref. 7). In the (100) plane, surface waves are confined to four wedges, of angle about 45°, containing the four-fold axes. There are five surface waves in directions near these axes and, as the wedges with no surface waves are approached, it can be seen that there are regions where progressively fewer such waves exist. All the waves contain components which decay sinusoidally. In the (110) plane, surface waves are propagated in all directions. Near the four-fold axis decay is simply exponential for all components; near the two-fold axis there is also some sinusoidal variation. Between these two axes there is a small range of directions where there are two waves with sinusoidal components and one wave without. The wave curves for both planes have cusps (corresponding to points of inflexion on the slowness curves). The Fourier transform method of solution gives the additional information that the rate of damping of amplitudes with distance travelled of waves in the cusp directions is of a lower order of magnitude than the rate of attenuation of waves in ordinary directions. If the distance from the source is r, in ordinary directions the amplitudes are proportional to $r^{-1/2}$, but in the cusp directions the amplitudes decay as $r^{-1/3}$.

CRYSTALLOGRAPHY

Molecular Geometry of a 1 : 1 Crystalline Complex between 1,3,7,9-Tetramethyluric Acid and Pyrene

As part of a research programme on the interaction between purine and polycyclic aromatic hydrocarbons, the crystal structures of molecular complexes between 1,3,7,9-tetramethyluric acid and pyrene, 3,4-benzopyrene and coronene, first described by Weil-Malherbe[1], are being investigated in our laboratory.

In a previous communication[2], the molecular packing in hydroxymethyl purine crystals was discussed with reference to the results of an X-ray determination of the crystal structure of 1,3,7,9-tetramethyluric acid. We wish to report here the most significant aspects of the molecular arrangement in a 1:1 complex between that acid and pyrene as

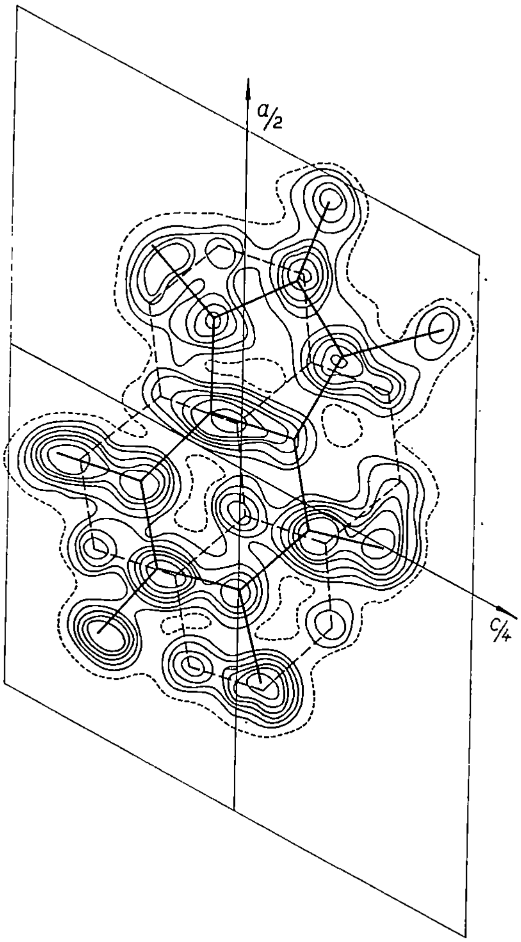

Fig. 1(*a*). Fourier projection of the electron density on (010)

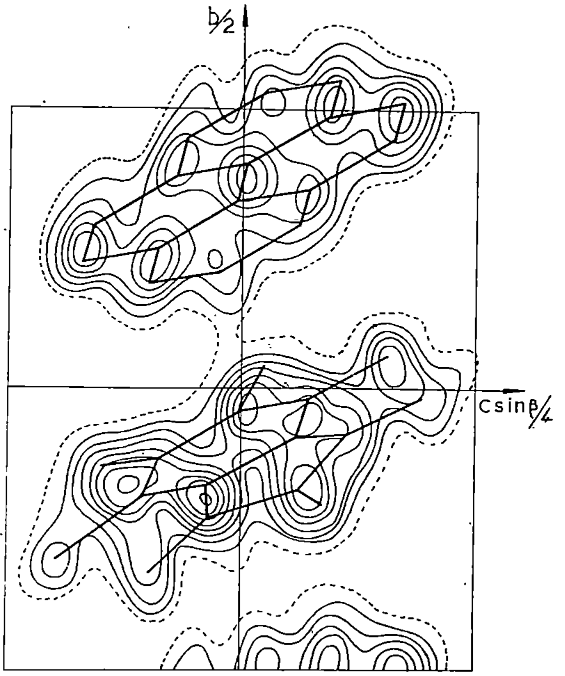

Fig. 1(*b*). Fourier projection of the electron density on (100)

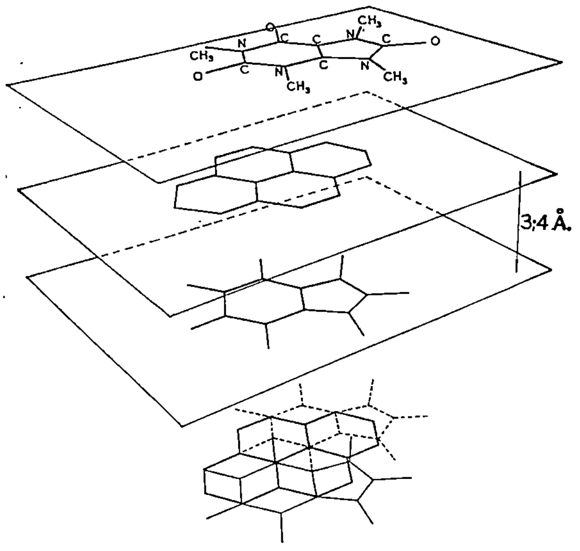

Fig. 2. Schematic drawing of the perpendicular separation of the molecules in one stack through the unit cell

revealed by an X-ray investigation of the crystal structure.

Two molecules of 1,3,7,9-tetramethyluric acid and two molecules of pyrene are contained in the unit cell of dimensions $a = 9{\cdot}71$ Å.; $b = 8{\cdot}00$ Å.; $c = 15{\cdot}04$ Å.; $\beta = 117°$. The space group is P/c—$C_s{}^2$ and the asymmetric unit contains one molecule of 1,3,7,9-tetramethyluric acid and one molecule of pyrene in general positions.

Fourier projections were calculated on (010) and (100) after the phases of a sufficiently large fraction of the observed reflexions had been established through a combination of optical Fourier transform and Patterson methods[3]. A refinement was then carried out through reiterate cycles of structure factor calculations on a 650 I.B.M. electronic computer up to a degree which was judged to be consistent with the complexity of the structure and the falling off of the intensities with the Bragg angle.

The most interesting feature of the crystal structure is a plane-to-plane alternate stacking of 1,3,7,9-tetramethyluric acid and pyrene molecules in infinite columns parallel to the b-axis. Two such columns run through the unit cell and are related to each other by a glide plane. A projection of the electron density on (010) and (100) is shown in Figs. 1(a) and 1(b).

In Fig. 2 the perpendicular separation and the relative orientation of 1,3,7,9-tetramethyluric acid and pyrene molecules in the complex is illustrated schematically. A graphite-like displacement from coincidence of the perpendicular projections of the atoms in one molecule with respect to the atoms in the next molecule may be noticed. This mode of packing is typical of molecular complexes the stability of which is commonly ascribed to 'polarization bonding'[4] between the components, the complexes between aromatic hydrocarbons and s-trinitrobenzene being a well-known example[5]. Weak charge transfer and dipole-induced dipole forces between the polar purine and the polarizable aromatic molecule, in addition to Van der Waals interactions, must therefore make the dominant contribution to the stability of the molecular complex between the acid and pyrene.

Just as in other similar cases, it is very likely that the relative orientation of the two components in the complex is the result of a compromise to produce maximum overlap between the π-orbitals involved in the electron transfer and between the polar regions of the purine and the polarizable regions of pyrene.

A correlation with other properties will be needed in order to try to assess the relative importance of the different forces contributing to the stability of the complex.

It may also be expected that the determination of the crystal structures of 2:1 complexes between 1,3,7,9-tetramethyluric acid and larger aromatic hydrocarbons in progress in our laboratory will be of considerable help in this respect, as well as in the elucidation of the mechanism of solubilization of polycyclic hydrocarbons in purine[1] and DNA water solutions (Liquori, A. M., Ascoli, F., Botrè, C., De Lerma, B., and Tresciotti, M., work to be published).

Full details of this work, which was supported by the Consiglio Nazionale delle Ricerche and by a grant from the Rockefeller Foundation, will be published shortly.

A New Technique for the Production of Synthetic Corundum

LARGE crystals of corundum have been grown for many years by the flame-fusion process originated by Verneuil[1]. Crystals coloured by small amounts of chromium, titanium, vanadium and other transition metal oxides are used in the gem industry and as jewel bearings and gramophone styli. The recent interest in ruby (chromium-doped corundum) as a paramagnetic material for use in masers and lasers has directed attention to the imperfections of the flame-fusion crystals. In particular, the inhomogeneity of chromium distribution in the crystals, the excessive residual strain and gross lattice imperfections detract from their usefulness in micro-wave and optical devices. Alternative methods of growth capable of giving better quality crystals are therefore of considerable interest for research in solid-state physics.

The hydrothermal growth of corundum has been accomplished (ref. 2 and Butcher, J., private communication, Hirst Research Centre of the General Electric Co., Ltd.), but considerable difficulties are involved in the production of good-quality crystals. It is necessary, for example, to work under conditions of high temperature and pressure where serious attack of conventional autoclave materials is experienced. The development of autoclaves of new design with heat-resisting alloys and inert metal liners is necessary, and the process is not yet suitable for the consistent production of large crystals.

Frémy and Feil[3] in 1877 produced small flakes of corundum from solution in lead oxide, but no further attempts to develop this method are recorded, and presumably after the success of Verneuil in 1890 the incentive to synthesize ruby was largely removed. The fluxed-melt technique for crystal growing has, in recent years, been revived for the laboratory production of comparatively large crystals of several inorganic oxide materials, for example, barium titanate, yttrium iron garnet and calcium tungstate[4].

Good-quality crystals of corundum, pure and doped with transition metal oxides, have now been produced from solution in lead fluoride. The process is carried out in a platinum crucible heated in a conventional laboratory furnace. The crystals are produced by spontaneous nucleation on slow cooling as hexagonal plates up to 2–3 cm. across. The thickness of the plates is largely dependent on the initial conditions of cooling, and in favourable circumstances they measure up to 1 cm. along the *c*-axis.

The crystals grow as truncated trigonal trapezohedra bounded by (0001) and $(10\bar{1}1)$ type faces, but $(10\bar{1}2)$ faces are occasionally observed. The surfaces of the latter appear roughened and they evidently disappear if the duration of growth is sufficiently prolonged. The $\{10\bar{1}2\}$ faces are thus more commonly observed on thick crystals, which require more growth perpendicular to the *c*-axis for these faces to grow out.

There is some tendency for the incorporation of lead fluoride in planes parallel to (0001); but many good-quality clear crystals, free from obvious faults, are obtainable.

The incorporation of high concentrations of paramagnetic ions can be readily achieved by this technique, and the products have the additional advantage of being strain-free.

RADIATION CHEMISTRY

Electron Spin Resonance Absorptions induced by Light in Adsorbed Layers of Cyanine Dyes on Silver Bromide Microcrystals

In connexion with the investigation of the mechanism of spectral sensitization of the photographic process, light-induced electron spin resonance absorptions in gelatinless precipitates of silver bromide dyed with cyanine dyes have been observed. No signals were detected under any conditions from the undyed silver bromide precipitates.

Electron spin resonance observations were made at 77° K. and at room temperature, utilizing the 100-kc./s. Varian *ESR* spectrometer. Samples were illuminated in the resonance cavity with a 500-W. tungsten lamp and a mercury-vapour lamp, from which light of selected wave-lengths was isolated by means of filters.

The sensitizing dyes examined constituted vinylogous series of quino-2,2′-cyanines and of thiacyanines. The dyes were (1) 1,1′-diethyl-2,2′-cyanine *p*-toluenesulphonate; (2) 1,1′-diethyl-2,2′-carbocyanine bromide; (3) 1,1′-diethyl-2,2′-dicarbocyanine bromide; (4) 3,3′-diethylthiacyanine bromide; (5) 3,3′-diethylthiacarbocyanine bromide; (6) 3,3′-diethylthiadicarbocyanine bromide; (7) 3,3′-diethylthiatricarbocyanine bromide; and (8) 3,3′-diethyl-9-methylthiacarbocyanine bromide.

Pure crystalline cyanine dyes (1), (2) and (4) did not exhibit detectable electron spin resonance absorptions under any conditions. Pure crystalline cyanine dyes (3), (5), (6), (7) and (8) exhibited absorptions at 77° K. and at room temperature, and also weak absorptions induced by light at 77° K.

Two reports[1] have appeared describing electron spin resonance at room temperature by crystalline dyes having extended systems of conjugated double bonds. The authors concluded that the observed absorptions were characteristic of long, unsaturated, conjugated chains, that they were not associated with excited states, and that they were possibly characteristic of the crystalline state of the conjugated dye molecules.

All precipitates of silver bromide containing adsorbed layers of each of these dyes (probably no more than a complete monolayer) exhibited at 77° K. narrow, structureless electron spin resonance signals at $g = 2{\cdot}005$ when exposed to light absorbed by the dye or by the silver bromide. In steady illumination, the electron spin resonance signals induced by light grew to an equilibrium intensity in about 4 min., and they decayed incompletely upon cessation of illumination if the temperature was maintained at 77° K. Warming the sample dissipated the light-induced signal completely. The cooling–illuminating–warming cycle was reversible and could be repeated many times, with no detectable change in behaviour of the samples.

The electron spin resonance response by the dyed precipitates exposed at 77° K. was greater in a vacuum than in an air atmosphere. Evacuated samples dyed with dyes (2), (6) and (8) showed weak, reversible, light-induced absorptions at room temperature; silver bromide dyed with dye (2) exhibited a weak, reversible, light-induced absorption in air at room temperature. Re-admission of air to an evacuated sample restored the sample to its original behaviour.

The action spectrum of the electron spin resonance signal induced by light and exhibited at 77° K. by an evacuated sample of silver bromide dyed with dye (8) was observed by utilizing for exposure narrow-band spectral regions isolated by means of interference filters. The action spectrum followed the long wave-length edge of the absorption band of the adsorbed dye through the maximum at about 610 mμ. The action maximum and the absorption maximum coincided within the limits of experimental error. On the short wave-length side of the maximum, however, the intensity of the electron spin resonance signal induced by light decreased with decreasing wave-length much more rapidly than the absorption of the adsorbed dye. The absorption of this dye at wave-lengths shorter than the maximum is in the form of an *H*-band. For some dyes, the sensitizing efficiency of light absorbed within their *H*-bands is known to be low[2]. Although the sensitizing efficiency of dye (8) is high in emulsions at room temperature at wave-lengths within the *H*-absorption band, it is suggested that at low temperatures the inefficiency of the *H*-band in sensitization, shown by some thiacarbocyanines, may overtake dye (8) and account for the feebleness of the electron spin resonance response to wave-lengths in the *H*-band.

The electron spin resonance signals induced by light shown by the dyed samples of silver bromide are much more intense than those exhibited by the pure crystalline cyanine dyes. There seems to be no doubt that these signals are associated with the adsorbed dye monolayer as it exists on the silver bromide crystallites. A weak signal induced by light was exhibited at 77° K. by a sample of lead bromide dyed with dye (1); this was very similar to the more intense signal induced by light and exhibited at 77° K. by silver bromide dyed with dye (1).

These observations seem to show without doubt that unpaired electrons, associated with the presence of an adsorbed layer of sensitizing dye on the surface of the silver bromide microcrystals, are produced by illumination of the sample with light absorbed by the dye. The conditions of the experiments preclude the possibility of detecting electron spin resonance absorptions by the triplet states of the dye molecules[3]. The observed electron spin resonance absorptions induced by light most probably arise from free radicals derived from dye molecules that are stabilized at low temperatures. The instability of the free radical derived from the dye molecule at room temperature, coupled with the lower sensitivity of the electron spin resonance spectrometer and the difficulties encountered in illuminating the samples, probably account for the negative results of the two earlier attempts[4] to detect electron spin resonance signals induced by light and exhibited by dyed silver bromide precipitates.

At present, the precise origin of the free radicals in these experiments cannot be stated. They may be the residue of dye molecules which have sensitized the silver bromide by transferring an electron into the conduction band of the crystal. But there are other possible modes of production of free radicals, for example, the action of bromine atoms on the adsorbed dye molecules. We hope to study such questions in the near future.

Radiolytic Oxidation of Ferrous Solutions with Standardized Internal Sources of Polonium-210

THE *G*-value of the oxidation in the aerated 'Fricke' dosimeter solution for irradiation with the α-particles of polonium-210 does not appear to be established accurately. Values ranging from 6·3 to 5·1 have been published with a tendency towards the lower figures as time progressed. The latest values, 5·5 and 5·1, published simultaneously by Lefort and Tarrago[1] and Trumbore and Hart[2] respectively, do not agree. We have redetermined this value by radiolysis with polonium-210 dissolved in 0·8 *N* sulphuric acid containing ferrous ammonium sulphate and sodium chloride both at a concentration of 10^{-3} *M*. The energy dissipated by radioactive decay, and absorbed by the system, was determined from standardization of the specific activity by 4π-internal liquid scintillation counting and an acceptance of the value 5·305 MeV. (ref. 3) for the energy of the polonium-210 particle. No account was taken of possible effects caused by the recoiling lead-206 nucleus.

Radiochemically pure polonium-210, obtained from the Radiochemical Centre, Amersham, was converted to nitrate-free sulphuric acid solution by thorough boiling with concentrated sulphuric acid. Since the polonium was added to the dosimeter solution carrier-free, it was necessary to establish that it stayed in solution in the strong acid medium without significant adsorption on the container walls. The percentage of radioactivity lost by adsorption was found to be totally insignificant in the range of surface-to-volume ratios of the glass apparatus used in this work. Irradiations were carried out at constant temperature in spherical flasks ranging in volume between 10 ml. and 500 ml. Owing to the small α-particle range in the solutions no significant loss of energy over the boundaries was expected or observed.

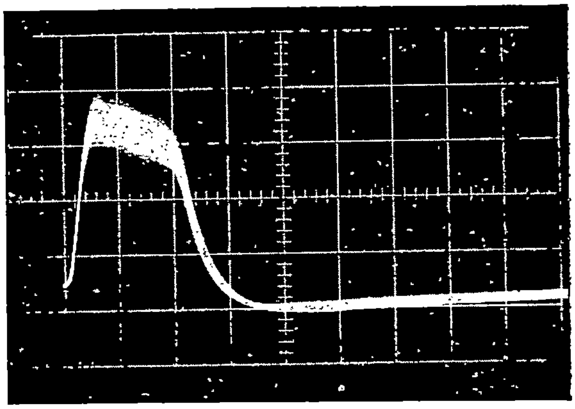

Fig. 1. Impulse spectrum, polonium-210 α-particles in the liquid scintillation counter

The specific activities of the dosimeter solutions after addition of the radioactivity varied between 9·8 μc./gm. and 25·6 μc./gm. Samples were taken at different times during the irradiations and diluted with 2 *N* hydrochloric acid to activity-levels convenient for counting. It was found that the polonium was very efficiently carried by the hydrochloric acid even after further dilution by the liquid scintillator, and no significant adsorption or precipitation was encountered during standardizations. The accuracy of the very convenient liquid scintillation method of precision α-particle counting has already been demonstrated by its use in half-life determinations[4]. Maximum error in counting measurements was well below 1 per cent.

Altogether five different irradiations were made yielding a mean *G*-value of:

$$5 \cdot 08 \pm 0 \cdot 02 \text{ ions per 100 eV.}$$

The error quoted is statistical only, calculated for a confidence limit of 68 per cent. Our result is thus in complete agreement with the value of Trumbore and Hart.

CHEMISTRY

Non-Uniformity of Cross-linking in Ion-Exchange Polymers

In theories of ion-exchange, the exchanger material is usually treated as a homogeneous phase, and transfer phenomena between the exchanger and aqueous solutions have always been explained on the basis of equilibria between two homogeneous phases. Recent experiments have shown that this simple picture cannot be maintained. The exclusion of co-ions by ion-exchangers in equilibrium with an aqueous solution, for example, the exclusion of cations by anion-exchangers with fixed cationic groups, or vice versa, has been well known for many years (for numerous references see the recent paper by Freeman[1]). Qualitatively this phenomenon is well understood on the basis of a Donnan equilibrium, which requires that the product of the ion activities of the electrolyte in the exchanger must be proportional to that in the solution. For a 1 : 1 electrolyte solution in contact with an anion-exchanger:

$$\underbrace{\underbrace{\{\bar{m}\}}_{\text{positive ions}} \cdot \underbrace{\{M+\bar{m}\}}_{\text{negative ions}}}_{\text{in exchanger}} = k \cdot \underbrace{\{m\}^2}_{\text{ion product in solution}} \qquad (1)$$

Hence, at low concentrations where $\bar{m} \ll M$, the uptake $\bar{m}$ of a 1 : 1 electrolyte like sodium chloride in an anion-exchanger of high fixed charge molality M should be proportional to the second power of the concentration, or more precisely, of the ion activity $(m\gamma)$ of this electrolyte in the equilibrating solution.

Verifications of this simple relation, however, have been far from perfect, largely due to the fact that it is difficult to remove quantitatively the aqueous phase from the surface of the exchangers. However, the conviction of research workers in the applicability of the Donnan law has always been sufficiently strong to introduce plausible though arbitrary correction terms, sufficient in number to restore the expected power law.

To overcome this experimental difficulty, a more refined measuring technique was introduced, in which amounts of electrolyte released from the equilibrated and wiped membrane into pure water are studied as a function of time. By extrapolating the observed curve back to zero time, according to the theoretical diffusion curve, it is then possible to eliminate the effect of the surface layer, which is released at the moment of immersion and does not affect the subsequent diffusion process. This permits an accurate analysis of the amounts of electrolyte taken up by the body of the exchanger independent of the amounts adhering to the surface. This, and the use of radiotracers, made it possible to measure the amounts of actual uptake over variations of more than 6 powers of ten. Fig. 1, curve *A*, shows the measured uptake results for sodium chloride on an A.C.I. anion exchanger membrane (made by the Asahi Chemical Industry Co., Ltd., Tokyo), with the uptake in equiv. per gm. of wet exchanger membrane plotted against the ion activity $m\gamma_{\pm}$ of the solution. This membrane is a homogeneous styrene–divinylbenzene co-polymer (approximately 8–10 per cent divinylbenzene) with quaternary ammonium groups and, when fully swollen, has a water content of 0·27 gm./gm. Instead of the expected proportionality of the uptake $\bar{m}$ with $(m\gamma)^2$, an exponent of 1·42 was observed.

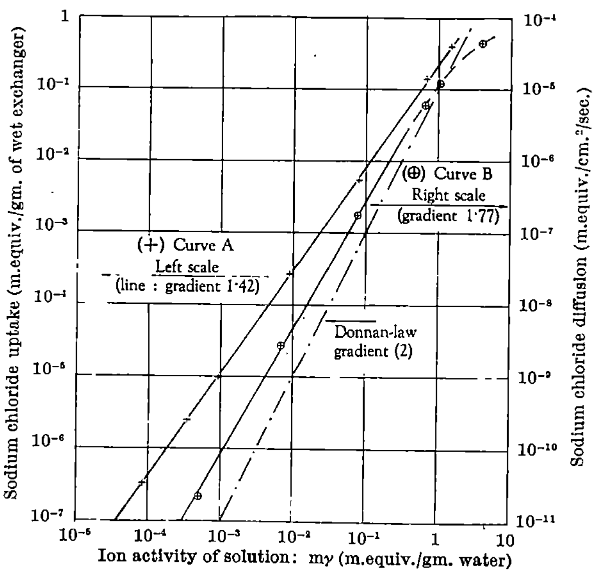

Fig. 1. Experimental determinations of electrolyte uptake and through-diffusion

The only rational explanation which will give a constant exponent over such a wide range of observations is that the exchanger is not a homogeneous phase, but that the fixed-charge density (and the cross-link density) in the exchanger varies continuously over a very wide range. Moreover, in order to give the fractional power law, the fixed-charge molality must vary in such a way that a fraction $d\varphi$ of the swollen exchanger has a fixed-charge molality between M and $M + dM$ defined by:

$$\frac{d\varphi}{dM} = K \cdot M^{-z} \qquad (2)$$

where K and z are constants, K being fixed by z and the experimental mean exchanger molality $\tilde{M}$. Then, if the appropriate Donnan relation is applied to each locality, and integration is carried out over the whole mass of the exchanger, one obtains a relation for the mean electrolyte uptake $\tilde{m}$ of the type:

$$\tilde{m} = K' \cdot (m\gamma)^{2-z} \qquad (3)$$

The results of Fig. 1 thus agree with this concept.

The observed behaviour of the electrolyte uptake is therefore a clear indication that the fixed charge molality M, and hence the distribution of cross-links in the exchanger polymer, is very far from uniform.

For the case investigated ($\tilde{M} = 4{\cdot}75$) the local fixed charge molality in the exchanger appears to vary from $M_{\text{max.}} \simeq 17$ to $M_{\text{min.}} < 10^{-4}$ equiv. per 1,000 gm. of swelling water, the distribution following equation (2) with $K = 0{\cdot}131$ and $z = 0{\cdot}58$.

The determinations of electrolyte uptake described, utilizing the diffusion release from the membrane, gave a clear indication that the apparent diffusion constant D' in the exchanger based on a Fick's law equation:

$$\frac{\partial c}{\partial t} = D' \cdot \frac{\partial^2 c}{\partial x^2} \qquad (4)$$

fell from 9×10^{-7} cm.²/sec. at $\tilde{m} = 0{\cdot}4$ m.equiv./gm. H_2O continuously to $1{\cdot}5 \times 10^{-7}$ cm.²/sec. at $\tilde{m} = 4 \times 10^{-7}$ m.equiv./gm. H_2O. As, at low uptake values, the ionic strength in an assumed homogeneous exchanger would be practically constant at $\tilde{M} = 4{\cdot}75$ m.equiv./gm. H_2O, there is no reason why in this case the true diffusion coefficient should change significantly. The obvious cause of the varying values of D' is that the exchanger is non-homogeneous. In this case the left side of equation (4) refers to the change in mean electrolyte concentration in the exchanger, while the concentration c on the right side refers to the concentration gradient in that fraction of exchanger which governs the diffusion process, namely, the more plentiful highly cross-linked fraction. Under these conditions, D', calculated according to equation (4), is not a true diffusion coefficient and it must vary in the observed direction.

On the basis of the foregoing explanation one would expect that steady-state diffusion through the membrane would be governed predominantly by the diffusion resistance of the highly cross-linked part, and this should follow a Donnan law more closely than the electrolyte uptake, which is largely influenced by the small fraction of low cross-link density. Experiments were carried out, therefore, in which the amount of diffusing electrolyte was measured, with one side of the membrane (thickness 0·019 cm.) in equilibrium with a solution of molality m, and with the other side washed with distilled water.

Fig. 1, curve B, shows the m.equiv. of sodium chloride diffusing per cm.² per second plotted against $m\gamma$ of the solution on a log-log scale. The diffusing amounts follow a power law of $(m\gamma)^{1{\cdot}77}$, thus showing a rather closer approach to the value of 2 expected for a homogeneously cross-linked system.

While the experiments (through the value of the constant z) give a clear indication of the degree of non-uniformity of the exchanger phase, they cannot decide the question of how it originated. A reasonable assumption would be that during the initial stages of the polymerization process, the divinylbenzene molecules combine preferentially with each other, leaving some very large chains of polystyrene with little cross-linking between them. Appropriate variations in the technique of manufacture combined with the analysis of non-uniformity by means of the determinations of electrolyte uptake described could throw some light on this question.

These investigations are being extended to other types of electrolytes and to other exchangers; these have so far shown a similar behaviour.

Quantitative Analysis of Milk and other Emulsions by Infra-Red Absorption

A BEAM of radiation passing through an emulsion can be attenuated by both absorption and scattering effects. Quantitative absorption measurements on such systems are only reliable when the effects of scattering are made small in comparison with those of absorption ; that is, when the ratio of the refractive indices of the two phases approaches unity and when the size of particle is considerably less than the wave-length. For milk, the ratio of the fat/serum refractive indices is approximately 1·1 and since the mean fat globule diameter of homogenized milk samples is about 1μ, scattering effects will be expected to be small at wave-lengths greater than 5μ. Homogenization will therefore reduce photometric errors caused by variations in the sizes of fat globules of milk samples from cows of different breeds and in different states of lactation.

Under suitable experimental conditions, the infra-red spectra of homogenized milk samples show absorption peaks near 5·8, 6·5 and 9·6μ, these bands being due mainly to the fat, protein and lactose components respectively. Except for the effects of the fat on the 6·5μ protein band, the interaction coefficients are small and, to a first approximation, the optical densities measured at 5·8 and 9·6μ are directly proportional to the concentrations of fat and of lactose.

Analysis of a series of milk samples of 20 cows of different breeds and in different states of lactation gave standard deviations of 3 per cent or better for all three components. The concentrations of fat and of lactose were estimated from the measured optical densities of the 5·8μ and 9·6μ bands, and the protein absorption at 6·5μ was corrected for changes in fat concentration as measured by the optical density at 5·8μ. Further corrections should reduce all these standard deviations, since 'synthetic' milk samples made by mixing varying amounts of cream and separated milk from the same bulk-milk sample gave a correlation of fat percentage and optical density at 5·8μ, which approached the limit of the photometric accuracy, namely, ± 1 per cent.

Milk samples were examined in a cell of path-length approximately 50μ, a similar cell containing water being placed in the solvent position of a double-beam spectrometer fitted with filters to remove stray radiation. Since the absorption by water was so intense at all three wave-lengths, only a few per cent of the total radiation was transmitted and the peak optical densities were about 0·2 for this path-length. Little improvement was obtained by increasing the path-length, since the reduced solvent transmission necessitated the use of a larger slit-width causing a decrease in resolution and increase in stray radiation. Except for the contribution of the protein to the 9·6μ lactose band, all the interaction coefficients were negative, indicating that the non-absorbing component had an apparent negative absorption effect due to displacement of the more intensely absorbing water molecules.

Fig. 1 illustrates part of the spectra of homogenized milk and separated milk, the negative absorption effect of the lactose and protein being apparent in the separated milk spectrum at 5·8μ.

Tests showed that a change in homogenization pressure from 50 to 200 kgm./cm.², giving a change of mean diameter of fat globules of 1 to 0·5μ, made no difference to the measured absorption intensities. Thus the scattering contribution was either constant,

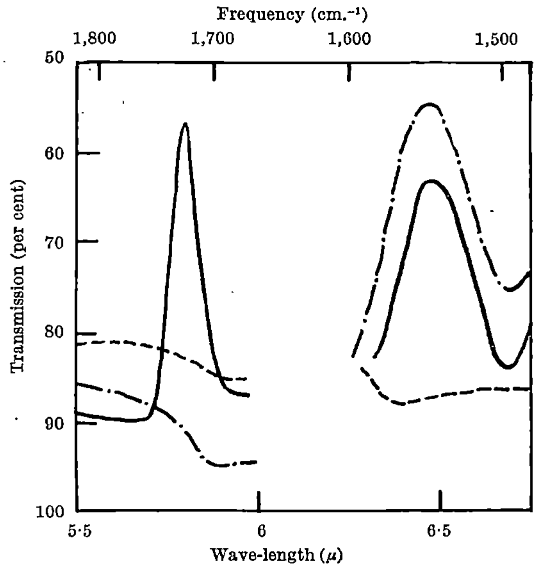

Fig. 1. Spectra of homogenized milk versus water (——), water versus water (– – –) and separated milk versus water (—·—·—). Path-lengths of approximately 50μ

or less than the limits of experimental error. Unlike previous turbidimetric methods for the analysis of milk, the infra-red absorption method is readily adapted to continuous recording of all three components, since the milk can be pumped directly from a small homogenizer into the infra-red absorption cell without dilution or addition of reagents. Further, the homogenizer is not required to operate under exactly reproducible conditions.

Analysis of hydrocarbon and other emulsions should be possible by use of the appropriate absorption bands, and samples of a few millilitres could be analysed using the small laboratory homogenizer described by Phipps[1]. Provided the sizes of the particles of the suspended phases were small enough, homogenized emulsions could be analysed directly by the infra-red absorption method.

This method is subject to U.K. Patent Application Nos. 3308/61 and 22,692/61, and full details will be published later (probably in *J. Dairy Res.*).

Detection by Ionization of Atmospheric Gases during Analysis by Gas Chromatography

WHEN small quantities of atmospheric gases are added to pure helium, the electrical conductivity of the helium increases. This effect forms the basis of a sensitive method for detecting these gases in the effluent of a gas chromatography column.

Berry[1], who used a Lovelock ionization detector[2] in conjunction with helium carrier gas, reported that painstaking purification of the helium was essential to obtain this effect. The work of Landowne and Lipsky[3] and Ellis and Forrest[4] tends to confirm this. These investigators reported obtaining decreases in ionization current with the addition of atmospheric gases when they used unpurified helium under otherwise similar experimental conditions.

By modifying the design of the detector cell so as to minimize contamination of the gas by air, we have achieved the effect and order of sensitivity reported by Berry although commercial helium without further purification was used. As the result of experiments in which the helium was deliberately contaminated, we were able to estimate that the purity required is not more than that specified for commercial helium.

The design of the detector cell is shown in Fig. 1. The central hole in the poly-tetrafluoroethylene insulator was drilled 0·010 in. smaller in diameter than the diameter of the anode pushed through it. The portion of the insulator projecting into the cathode cylinder was machined to a diameter 0·008 in. greater than that of the cylinder into which it was forced. The outlet of the detector cell is 0·050 in. inner diameter tubing at least one inch long to minimize back diffusion of air. In this detector cell, the junctions of insulator and electrode surfaces were capable of withstanding at least two atmospheres of gas pressure without apparent leakage. This is the only apparent significant difference between this design and that of Lovelock[2,5].

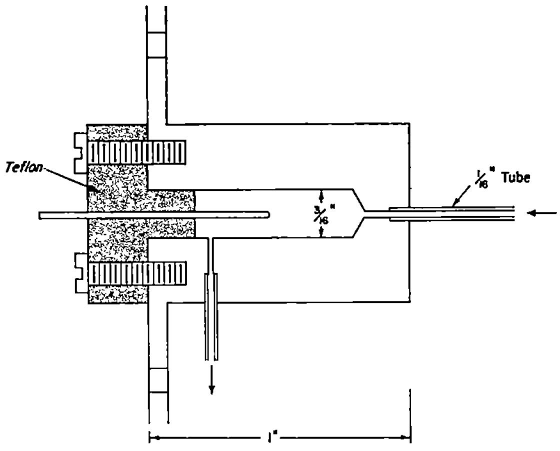

Fig. 1

We chose to operate this detector cell so that the voltage across it was recorded while 1 μamp. from a source of constant current flowed through it. Under these conditions, a decrease in voltage, rather than increase in ionization current, indicates an increase in the electrical conductivity of the gas. This mode of operation is very convenient, makes the presence or absence of a radioactive source in the detector immaterial, and extends the dynamic range of the detector when decreases in the conductivity of the gas are to be followed. Qualitatively comparable results were obtained by impressing 400–600 V. across a similar detector containing a tritium foil and monitoring the current.

Table 1

Gas	Initial sensitivity (V./volume per million volumes of helium)	Increment of concentration for max. conductivity of the mixture (volumes per million volumes of helium)	Peak change in conductivity (V.)
Oxygen	11	280	180
Nitrogen	4	520	250
Argon	3	960	270
Carbon dioxide*	5	80	184

* Determined using silica-gel column.

The response of the detector was determined for oxygen, nitrogen, and argon analysed using a column containing a Linde molecular sieve 5*A*. Carbon dioxide was analysed using columns containing silica gel. As the concentration of each of these gases in the helium increased, the electrical conductivity of the mixture increased, reached a maximum, and then decreased. The sensitivity, the concentration of each gas necessary to bring the conductivity of the binary mixture with helium to a maximum and the electrical conductivity at that maximum varied among the different gases. Values for these parameters under one set of experimental conditions are shown in Table 1. The stability of the system is such that random noise is less than 0·1 V., from which the ultimate sensitivity of the detector may be estimated.

Commercial helium is specified to be at least 99·99 per cent pure[6]. From the increases in concentration of contaminating gases required to bring helium to maximal electrical conductivity, one would infer that the purity of the helium is less significant than the experimental conditions in determining whether the conductivity will increase or decrease on the addition of permanent gases. In our experience the response was determined largely by the design and construction of the detector cell.

Effect of Ozone on the Fluorescence and Ultra-violet Absorption Spectra of 3,4-Benzopyrene

PREVIOUS investigations concerning the quantitative determination of the 3,4-benzopyrene content of the air by fluorescence emission spectroscopy[1] showed that the fluorescence intensity of the samples exposed for some hours to air decreased markedly. Experiments were carried out with benzene solutions of 3,4-benzopyrene to investigate this effect. Standard concentrations of 1·2, 12, 120 and 1,200 μgm./ml. were prepared. Ozone was generated in an experimental chamber with an electric spark generator, Kocsis system, and the ozone-contaminated air of the chamber was aspirated through an impinger filled with 6 ml. solution. The ozone content was determined with 2 *N* potassium iodide by the analytical method described by Thorp[2]. The fluorescence emission spectra of the 3,4-benzopyrene solutions were taken with a fluorescence spectrophotometer specially designed for these investigations by one of us. At the same time, the ultra-violet absorption of the samples was measured with a Beckman *UD* spectrophotometer.

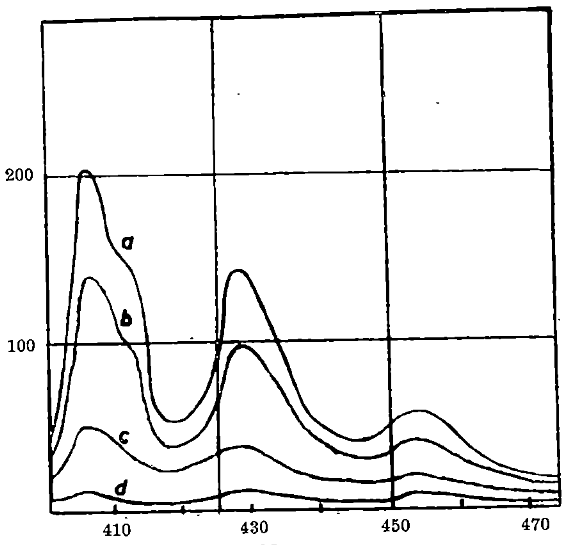

Fig. 1

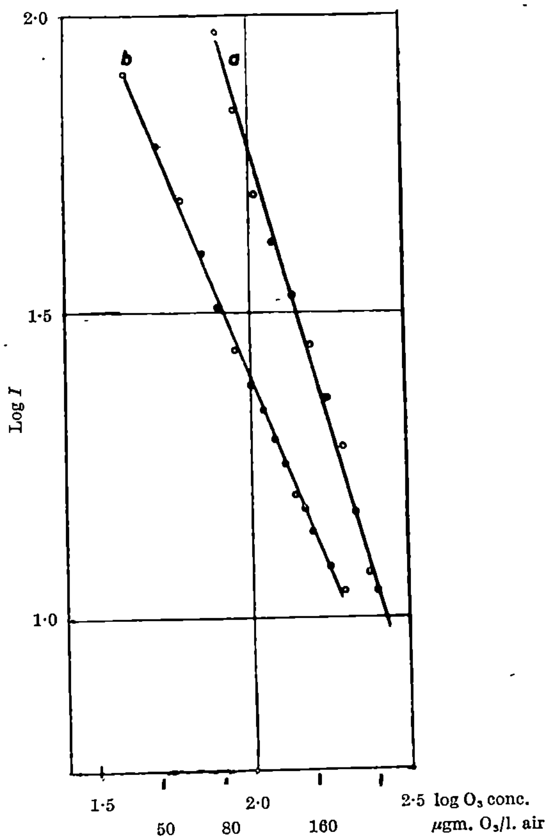

Fig. 2

Fig. 1 shows that, as a result of the ozone treatment, the fluorescence of the samples decreased with increasing time of treatment, that is, increasing amount of ozone introduced into the samples. Curve *a* of Fig. 1 refers to the fluorescence before the ozone treatment, *b* to that after 3 min. aspiration (33 μgm. ozone/l. air), *c*, after 7 min. (104 μgm. ozone/l. air), and *d*, after 10 min. treatment (255 μgm. ozone/l. air). At the same time, the absorption peaks decreased too. If the ozone treatment continued long enough, fluorescence and absorption were extinguished. The time necessary to decrease the initial fluorescence peaks to a tenth of their original value appeared to depend on concentration, and for larger concentrations on wave-length with shorter decay times of peaks at 406 mμ. The process of decreasing fluorescence intensity can be accounted for by a bimolecular law, since the logarithm of the peak intensity versus the logarithm of the ozone concentration gives straight lines (Fig. 2: *a* refers to the peak at 406 mμ; *b*, to the peak at 428 mμ).

1,200 μgm./ml. concentrations were crystallized from solution after, as a result of the treatment with ozone, the fluorescence was extinguished. Microscopical investigations showed a structural difference between the ozone treated and the original crystals. Electron diffraction patterns taken with a Hitachi electron microscope operated at 75 kV., 50 m.amp., give a marked difference too. The melting point of the ozone-treated crystals was not sharply defined (110–130° C.) whereas the melting point of 3,4-benzopyrene crystals is 176° C.

A detailed account of this work will be published elsewhere. We thank Dr. J. Mórik for valuable discussions and J. Dvorzsák for his assistance in taking the electron diffractograms.

Supercontraction of Iodinated Wools

Haly and Feughelman[1] have shown that iodination of wool, when using ethyl alcohol as the solvent, causes a large reduction in the rate of second-stage supercontraction. They express the opinion that "it does seem possible that iodination of tyrosine (or other) residues could, through steric hindrance, make movement of groups, and therefore disruption, more difficult". Leveau *et al.*[2] attributed the lowering of the urea–bisulphite solubility of the iodinated wools to a strengthening of the hydrogen bonds of the phenolic hydroxyl groups by the substitution of the halogens on the tyrosine molecules. In a recent publication the explanation was offered by me[3] that the decrease in supercontraction of the second stage by iodination was due to the steric hindrance caused by the two bulky iodine atoms substituted in the 3,5 positions on the tyrosine molecule, whereby the partially hydrated lithium ion, with its comparatively large volume, is prevented from reaching the hydrogen bonds formed by the hydroxyl group. These hydrogen bonds will therefore remain intact during the supercontraction reactions and the subsequent restriction of the movement of the chains will reduce the rate of disulphide interchange taking place, thus reducing the rate of second-stage supercontraction.

While investigating the ability of different alcohols to penetrate into keratin fibres, Harrison and Speakman[4] found that fibres treated with a solution of iodine in either methyl alcohol or ethyl alcohol undergo total iodination of the tyrosine residues present in the keratin. Butanol and higher alcohols do not penetrate the fibre at all and, consequently, iodination with these higher alcohols as solvents for the iodine is effective for less than 1 per cent of the tyrosine residues present. When the iodine is, however, dissolved in *n*-propyl alcohol the reaction was shown to proceed to a point where about one-third of the tyrosine residues in the keratin could be accounted for. Haly and Feughelman[5] investigated the X-ray diffraction patterns of wools iodinated with an ethanolic and an *n*-propanolic solution of iodine respectively, and concluded that both ethanol and propanol solutions iodinate tyrosine residues in the matrix, but only the ethanol solution produces iodination of tyrosine in the microfibrils.

The series zone model for ketatin fibres[6] explains many of the physical properties of animal fibres, such as the two-stage supercontraction in concentrated solutions of lithium bromide at elevated temperatures and the stress–strain behaviour. According to this model, the matrix plays no part in the supercontraction, contraction occurring exclusively in the microfibrils. The two different kinds of zones occurring alternately along the length of the microfibrils are responsible for the two distinct contraction stages.

In view of this theory, it seemed appropriate to investigate whether selective iodination of the matrix alone would have any influence on the supercontraction of the fibres.

One end of a 1-cm. section from the root end of a 64's Merino wool fibre which had previously been washed in petroleum ether, ethanol, 1 per cent aqueous solution of 'Lissapol' (I.C.I.), water, ethanol and ether successively, was attached to a glass rod with molten polystyrene. A snippet, 0·5 mm. in length, was cut from the free end of this fibre section and supercontracted at 90° C. in an unbuffered 7·8 *M* lithium bromide solution, using the technique of Haly and Griffith[7]. The fibre section remaining on the glass was then iodinated in the way described in ref. 4. Special care was taken to ensure that the fibre section was absolutely dry and that the propyl alcohol contained no lower homologues or water. The iodination reaction was allowed to proceed for 14 days at 22° C., after which it was washed with sodium thiosulphate solution and water. After drying in a stream of cold air, a 0·5-mm. snippet was again cut off from the free end of the section and supercontracted. This procedure ruled out the variations, with regard to supercontraction, found along the length of the fibre as the two snippets were adjacent in the original fibre and with a total length of only about 1 mm.

Four determinations were carried out in this way using four different wool fibres. In none of these cases could any significant difference be detected between the supercontraction curves before and after iodination in the presence of *n*-propyl alcohol.

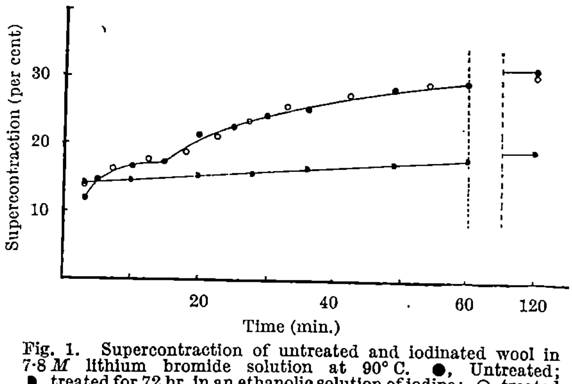

Fig. 1. Supercontraction of untreated and iodinated wool in 7·8 *M* lithium bromide solution at 90° C. ●, Untreated; ◗, treated for 72 hr. in an ethanolic solution of iodine; ○, treated for 14 days in an *n*-propanolic solution of iodine

The accompanying graph shows the kinetic supercontraction of untreated wool and wool iodinated with an *n*-propanolic solution of iodine in comparison with wool treated with a solution of iodine in ethanol for 72 hr.

The results are in agreement with the X-ray results in that the matrix alone is iodinated with the *n*-propanolic solution, with no effect on the supercontraction, while almost total iodination of matrix and microfibrils is achieved by using ethanol as the solvent, resulting in a marked depression of the second-stage supercontraction.

BIOCHEMISTRY

Identification of a Compound related to 6-Aminopenicillanic Acid, isolated from Culture Media of *Penicillium chrysogenum*

It has previously been reported[1] that when a high-yielding strain of *Penicillium chrysogenum* was grown in shake flasks in a chemically defined arginine-lactose medium[2] containing sodium sulphate labelled with sodium-35 in the absence of phenylacetic acid, a radioactive compound extractable with *n*-butyl-acetate was formed instead of benzylpenicillin. This compound differed in its chromatographic properties from any of the known penicillin degradation products.

Afterwards it was found that this compound was also formed when the mould was grown in stirred 90-l. fermenters under standard conditions, using the vortex system of aeration on a chemically defined ammonium acetate – ammonium lactate – lactose medium[3], and this made it possible to isolate the compound in larger amounts and to elucidate the structure. This work is reported in the present communication.

Isolation: The culture medium (50-l. per fermenter) was gathered after 4 days fermentation (aeration condition: vortex system, eight-bladed turbine stirrer 130 mm. diam., 700 r.p.m., air flow 50 litres per min.), filtered, cooled to 5° C., acidified to *p*H 2, extracted, first (to remove traces of penicillin) with half a volume of chloroform in which the compound is insoluble, and then three times with two volumes of *n*-butyl acetate to remove the compound. The partition coefficients of the compound in different solvents were established in preliminary experiments in which labelled sodium sulphate was added to the culture medium and the distribution in solvents followed by measuring the radioactivity. The compound was transferred from the solvent into one quarter of its volume of water by adjusting the *p*H to 7, the aqueous solutions concentrated *in vacuo* at 40° C., cooled to 5° C., acidified to *p*H 2, and percolated through a column of granular charcoal. The adsorbed compound was fractionally eluted by 70 per cent aqueous ethanol; iodine titration was used for detecting the compound in the different fractions. The fractions containing the compound were concentrated *in vacuo* for complete removal of ethanol, an excess of *N,N'*-dibenzylethylenediamine added, and, after ether extraction, the aqueous solution was concentrated to an oil. The crystalline *N,N'*-dibenzylethylenediamine salt, melting point 110–114° C., was obtained by dissolving the oil in a minimal amount of hot water, adding acetone and cooling slowly. The dried salt was hygroscopic (found: C, 59·04; H, 6·65; N, 11·14; S, 6.40; O (direct determination), 17·00 per cent; $C_9H_{12}O_5N_2S,C_{16}H_{20}N_2,1/2H_2O$; requires: C, 58·92; H, 6·52; N, 11·00; S, 6·29; O, 17·27 per cent). The yield was about 20 mgm./l. of culture medium. Altogether, about 25 gm. of *N,N'*-dibenzylethylenediamine salt were prepared.

The free acid was obtained from this salt by passing an aqueous solution cooled to 5° C. through a cation exchange column of 'Amberlite *IR* 120'(H) and lyophilizing the percolate. The amorphous powder was hygroscopic (found: C, 39·61; H, 4·81; N, 9·76; S, 11·35 per cent; $C_9H_{12}O_5N_2S,1/2H_2O$ requires: C, 40·14; H, 4·87; N, 10·40; S, 11·91 per cent; $C_9H_{12}O_5N_2S,1H_2O$ requires: C, 38·84; H, 5·07; N, 10·07; S, 11·52 per cent). The free acid could be obtained crystalline from ether. Analysis suggested the presence of one mole of ether of crystallization, which was firmly bound; it was retained even on heating at 100° C. at 15 mm. pressure, but was lost on heating to the melting point (loss of weight roughly equivalent to one mole of ether). The compound effervesced between 110 and 120° C., losing its crystalline structure, and melted at 140° C. (for two different samples, found : C, 45·85, 45·79; H, 5·98, 6·37; N, 8·81, 8·73; S, 10·29, 9·68 per cent; $C_9H_{12}O_5N_2S,(C_2H_5)_2O$ requires: C, 46·69; H, 6·63; N, 8·38; S, 9·59 per cent). A crystalline dimethyl ester was obtained by adding an ethereal solution of diazomethane to a solution of the free acid in ether-ethanol, evaporating to dryness and recrystallizing from ethanol. It had a melting point of 168–170° C. (found: C, 45·64; H, 5·61; N, 9·92; S, 10·96 per cent; $C_{11}H_{16}O_5N_2S$ requires: C, 45·82; H, 5·59; N, 9·72; S, 11·12 per cent).

Elementary composition. The analyses of the *N,N*-dibenzylethylenediamine salt, the free acid, and the dimethylester indicate the formula of this compound to be $C_9H_{12}O_5N_2S$.

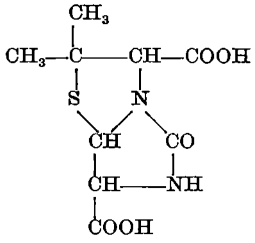
Properties. The compound is a dibasic acid, having *pK* values of 2·5 and 3·4 as determined by electrometric titration. It gives no colour reactions with hydroxylamine-ferric chloride, nitroprusside or ninhydrin. It is strongly dextrorotatory, $[\alpha]^{26}_{D} = +282°$ ($c = 1·2$, in water), as are the *N,N'*-dibenzylethylenediamine salt, $[\alpha]^{23}_{D} = +160°$ ($c = 1·0$, in water) and the dimethylester, $[\alpha]^{23}_{D} = +218°$ ($c = 1·4$, in ethanol). It has no characteristic ultra-violet absorption in the *p*H range of 1–14. With mercuric chloride it gives a precipitate which, after decomposition with hydrogen sulphide, gives a product showing a positive reaction for sulphydryl groups with ferric chloride, but a negative ninhydrin reaction. The original compound reacts with iodine, taking up six equivalents of iodine per mole, and this reaction can be used for its quantitative determination.

Degradation. On heating with 1 *N* hydrochloric acid for 20 min. one mole of carbon dioxide is evolved, and a compound is obtained which, after crystallization from ethyl acetate, has a melting pioint of 173–175° C. (found: C, 44·64; H, 5·73; N, 13·22; S, 14·89 per cent; $C_8H_{12}O_3N_2S$ requires: C, 44·43; H, 5·59; N, 12·95; S, 14·83 per cent). This compound is a monobasic acid ($pK = 3·4$) giving no ninhydrin or sulphydryl reaction. It precipitates with mercuric chloride and reduces iodine. Its methyl ester, prepared by treatment with diazomethane, has a melting point of 130° C. after crystallization from carbon tetrachloride-light petroleum (found: C, 47·22; H, 6·34; N, 12·31; S, 14·18 per cent; $C_9H_{14}O_3N_2S$ requires: C, 46·94; H, 6·13; N, 12·17; S, 13·92 per cent).

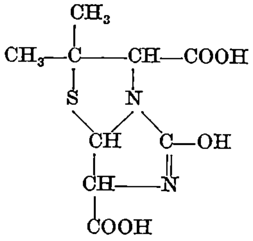
On oxidation with sodium periodate or hydrogen peroxide or bromine water followed by hydrolysis (6 *N* hydrochloric acid, 7 hr. at 105° C.), the compound produces two ninhydrin-positive substances which were identified by paper electrophoresis and by paper chromatography (in eight solvents) as penicillaminic acid, $(CH_3)_2C(SO_3H)CH(NH_2)COOH$, and glycine. Acid hydrolysis without previous oxidation gave a more complex mixture of degradation products.

Structure. With the isolation of penicillaminic acid, glycine and carbon dioxide, 8 of the 9 carbon atoms and 4 of the 5 oxygen atoms of the compound were accounted for, as well as their sequence; the four oxygen atoms form part of the two carboxylic groups revealed by electrometric titration.

From this as well as chemical and physical properties the most likely formula for the compound is that of the imidazolidone I (2,2-dimethyl-5-oxo-hexahydro-imidazo [5,1-*b*]-thiazolo-3,7-dicarboxylic acid), or its imidazoline tautometer II indicated below; that unaccounted-for carbon and oxygen forming the CO link between the two nitrogens.



(I)



(II)

Structure II is a penillic acid type of compound in which the penicillin side-chain residue is replaced by OH.

This structure is confirmed by the fact that the dimethylester of the compound as well as the methyl ester of the decarboxylated compound have properties identical to those reported in the literature for products previously obtained by unequivocal syntheses[4,5].

During the course of this work it became clear that the compound described here was identical with the compound VI of Tardrew and Johnson[6].

Mode of formation. Synthesis of this compound was attempted by treating phosgene with 6-amino-penicillanic acid which had previously been incubated in alkaline solution to destroy the β-lactam ring. Best results were obtained by using aqueous bicarbonate solutions, and paper electrophoresis of samples taken both before and after the addition of phosgene revealed that a substance with the same mobility as the natural compound was formed immediately on dissolving 6-amino-penicillanic acid in aqueous sodium bicarbonate. High yields of the synthetic compound were obtained by passing a stream of carbon dioxide into a solution of 6-aminopenicillanic acid in potassium phosphate buffer, *p*H 7·0. The *N,N′*-dibenzylethylenediamine salt prepared from the product of this reaction has properties identical with those of the salt of the naturally occurring compound (optical rotation, paper chromatographic mobility, melting point, infra-red spectrum).

The reaction of 6-aminopenicillanic acid in bicarbonate solution to yield a compound identical with that described in the present communication has independently been observed by Drs. Batchelor and Rolinson of Beecham Research Laboratories (personal communication to E. B. Chain; see following communication).

Thus, it appears that the compound is formed by carboxylation of the amino group of 6-amino-penicillanic acid followed by a penillic acid rearrangement. The rearrangement was hitherto only known to occur at acid *p*H.

We wish to thank Drs. R. Falini and F. Ricci and the staff of the pilot plant for their invaluable help, and Drs. Margherita Marzadro and Lavinia Carta De Angeli for analytical determinations.

The compound was isolated by Ballio, Chain, di Accadia, Mauri, Rauer and M. J. Schlesinger. The chemical investigations were carried out by Ballio, Chain, Schlesinger and S. Schlesinger.

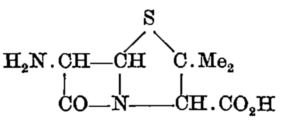
Action of Carbon Dioxide on 6-Aminopenicillanic Acid

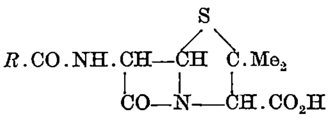
THE nucleus of the penicillin molecule, 6-amino-penicillanic acid (I)[1], is in some respects more stable than most penicillins (II), being, for example, only slowly destroyed by mineral acids. It was therefore surprising to find that carbon dioxide, which is without effect on penicillins, readily attacked 6-amino-penicillanic acid to yield a product which could no longer be converted into penicillins by acylation. The effect was first observed when 6-aminopenicillanic acid was dissolved in water by neutralization with sodium bicarbonate, but a solution of sodium 6-aminopenicillanate in aqueous sodium bicarbonate was much more stable, indicating that the reaction required free carbon dioxide. When carbon dioxide was bubbled continuously through an aqueous solution of 6-aminopenicillanic acid at 37° C. and an initial *p*H of 7·0 the 6-aminopenicillanic acid content, determined by phenylacetylation followed by biological assay, fell by 50 per cent every 3 hr. The hydroxylamine assay[2] and the leucine equivalent as determined by ninhydrin fell at the same rate, indicating that both the β-lactam ring and the amino-group were absent from the reaction product.

For preparative purposes carbon dioxide was bubbled through a 2 per cent solution of 6-aminopenicillanic acid until more than 90 per cent had been destroyed, and the resulting solution was passed through a column of 'Amberlite *IR*/120'(H) to remove sodium ions and residual starting material. Freeze-drying then gave a strongly acidic white solid (70 per cent yield) which was very soluble in water and polar solvents, but insoluble in non-polar solvents. Neither the acid nor its salts could be recrystallized; but analysis of the amorphous material, which had no definite melting point, indicated that it was derived from 6-aminopenicillanic acid by the addition of one molecule of carbon dioxide. (Found: C, 39·5; H, 4·7; N, 10·3; S, 12·0. $C_9H_{12}O_5N_2S$, $0·5H_2O$ requires C, 40·1; H, 4·9; N, 10·4; S, 11·9 per cent.)

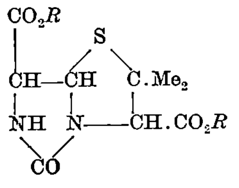
The substance appeared to contain a labile carboxyl group since one molecule of carbon dioxide was lost when the acid was: (*a*) treated at room temperature with mercuric chloride solution or (*b*) dissolved in water and boiled for 2–3 hours. The product from (*b*) was isolated in 84 per cent yield and crystallized from water in colourless rosettes, m.p. 175–176° C., of a monocarboxylic acid isomeric with 6-aminopenicillanic acid (found: C, 45·0; H, 5·9; N, 12·8; S, 14·9; $C_8H_{12}O_3N_2S$ requires C, 44·4; H, 5·6; N, 13·0; S, 14·8 per cent). These properties suggested that the original carbon dioxide adduct was a dicarboxylic acid closely related to the penillic acids[3], most probably 2,2-dimethyl-5-oxohexahydro-imidazo-[5,1-*b*]-thiazole-3,7-dicarboxylic acid (III; *R* = H). Methylation with diazomethane in the usual way confirmed this structure, giving 68 per cent of the ester (III; *R* = Me) which crystallized from water or ethyl acetate in needles, m.p. 166–167° C., $[\alpha]^{21}_{D}$ + 220° ($c = 0·5$ in EtOH) (found: C, 46·0; H, 5·8; N, 9·4; S, 11·0; calc. for $C_{11}H_{16}O_5N_2S$: C, 45·8; H, 5·6; N, 9·7; S, 11·1 per cent). The decarboxylation product, 2,2-dimethyl-5-oxohexahydro-imidazo-[5,1-*b*]-thiazole-3-carboxylic acid (IV; *R* = H) was similarly converted in 90 per cent yield to the ester (IV; *R* = Me) which crystallized from water in needles, m.p. 129–130° C. (found: C, 47·2; H, 6·4; N, 12·3; S, 13·9; calc. for $C_9H_{14}O_3N_2S$: C, 46·9; H, 6·1; N, 12·2; S, 13·9 per cent). From their physical properties, these esters would appear to be identical both structurally and stereochemically with specimens previously prepared by synthesis from D-penicillamine methyl ester[4].



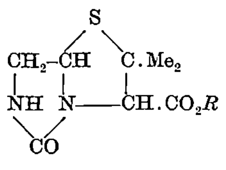
(I)



(II)



(III)



(IV)

The facile formation of (III; *R* = H) from (I) in essentially neutral solution may involve formation of the carbamic acid (II; *R* = OH; 'hydroxypenicillin') followed by penillic rearrangement[5], although the latter normally occurs only at low *p*H. Alternatively, there may be a concerted attack by the carbon dioxide molecule on both the amino group and the highly reactive cyclic amide functions.

None of the derivatives described here exhibited antibacterial activity.

We wish to thank Prof. E. B. Chain, for helpful discussions (see preceding communication).

Extraction of Lipids from the Precursor of the Stylet-Sheath Material of a Pentatomid

It has been reported[1] that the stylet-sheath material of the American milkweed bug, *Oncopeltus fasciatus* (Dall.), yields oily sudanophil droplets when warmed in chlorated nitric acid. In the three-lobed principal salivary glands, the contents of the anterior and lateral lobes have been identified as the precursors of the sheath material, and the contents of the lateral lobe show stronger sudanophilia than the contents of the other lobes[2]. On this evidence, it was suggested that lipid is present in the sheath material and is elaborated in the lateral lobe; and on the basis of the reaction of *Oncopeltus* sheath material to the Liebermann–Burchardt test for sterols, it was concluded that a steroid might be present. The following concerns the presence of lipids in the sheath material and its precursor in the salivary glands of an Australian pentatomid, *Eumecopus* sp., which feeds on eucalypts.

The sheath material of *Eumecopus* also produced oily sudanophil droplets when warmed in chlorated nitric acid. The principal salivary gland is bilobed. The contents of the anterior lobe could be distinguished from the contents of the posterior lobe and identified as the precursor of the sheath material by the immediate coagulation of the contents of the anterior lobe in water, physiological saline, and glycerol; the production of oily droplets when the contents of the anterior lobe were warmed in chlorated nitric acid; and the ability of toluidine blue to stain the contents of this lobe the same characteristic turquoise-blue colour as it did sheath material. The precursor could be collected in much larger quantities than the sheath material itself, and an attempt was made to extract lipids from the precursor with organic solvents.

The contents of the anterior lobes of several glands were first gelled by immersing the glands in glycerol. When transferred to water the glands swelled, causing the walls of the anterior lobes to separate from the coagulated masses of sheath precursor. These were removed from the glands, freed of adherent cellular material, washed thoroughly, and dried. About 5 mgm. were sealed in a capillary tube with about 15 µl. of a 4 : 1 mixture of chloroform and methanol, and incubated at 60° C. for 18 hr. When the solvent was removed and evaporated, it was found that approximately 350 µgm. of a grease-like material had been extracted. Preliminary tests on smears of the grease either on slides or filter paper showed that the extracted material was strongly fluorescent; had a strong affinity for the sudan colorants for lipids; was coloured blue by nile blue sulphate, suggesting the presence of acidic lipids; gave a positive test for amines with ninhydrin; and gave a positive result for 'Lipine' with Baker's acid hæmatin test[3] and for phosphate with a modified Hanes–Isherwood reagent[4] in an atmosphere containing hydrogen sulphide. When run in a test-tube paper-chromatogram, using *n*-butanol/acetic acid/water (4 : 1 : 5) as solvent, fluorescent material was carried to the solvent front and gave a positive reaction with ninhydrin and Hanes–Isherwood reagent, while substances giving reactions with either or both reagents were left in the path of the solvent. With the Liebermann–Burchardt test, the grease gave a purple-brown colour which developed and faded slowly; no positive reaction was obtained with other colour tests for unsaturated steroids[5].

These results suggested the presence of phospholipid and related compounds, and separation of the grease into components was attempted by treating it with different solvents. These extracts were spotted on filter paper previously soaked in a large volume of chloroform–methanol, and further separation was attempted either by allowing another solvent to run past the spot by capillary ascent or by running test-tube paper-chromatograms.

A water extract run in butanol/acetic acid/water gave a faint spot with ninhydrin about one-third the distance from the origin to the solvent front, and a blue ring with Hanes–Isherwood reagent just above the origin.

An acetone extract was further separated with benzene. The benzene-soluble fraction gave no reaction with ninhydrin or Hanes–Isherwood reagent, but took up sudan colorants and coloured blue with nile blue; it ran with the solvent front in butanol/acetic acid/water and was probably fatty acid. The benzene-insoluble fraction gave at the most a brown colour with Hanes–Isherwood reagent, and was barely coloured by nile blue or the sudan colorants, but gave a reaction with ninhydrin, even after repeated washings with water.

A benzene extract of the original grease, when run in butanol/acetic acid/water, gave a large spot with ninhydrin near the solvent front and other faint spots along the path of the solvent; a streak coinciding with ninhydrin-positive material near the solvent front gave a positive reaction with Hanes–Isherwood reagent and was coloured blue by nile blue. The material near the solvent front thus gave the reactions of a phospholipid. However, fluorescent material which remained at the origin and showed no reaction with ninhydrin or Hanes–Isherwood reagent was coloured blue by nile blue and took up the sudan colorants, suggesting that a lipid other than phospholipid was also present.

These experiments showed that lipid is present in the stylet-sheath material of *Eumecopus* and in the precursor elaborated in the anterior lobe of the salivary glands. The lipid extracted from the precursor is partly phospholipid, but there was evidence of the presence of other lipid substances. However, in contrast to the reaction of the sheath material of another plant-bug, *Oncopeltus fasciatus*, to the Liebermann–Burchardt test, the reaction of *Eumecopus* sheath material was negative; and no specific steroid reactions were obtained in the grease extracted from the precursor.

A Selective Toxin produced by *Periconia circinata*

Toxins with species and varietal specificity have often been postulated, but so far only one such substance has been isolated from a plant pathogen[1]. *Helminthosporium victoriae*, causal agent of a blight of certain oat cultivars, produces an extremely powerful exotoxin which has the same specificity for plants as does the fungus itself. Thus, the *Helminthosporium* blight is a valuable model for study of the biochemistry of disease. However, there are difficulties; most strains of the fungus give low yields of toxin *in vitro*, and the compound is very unstable[2]. Isolation of other selective toxins might overcome such difficulties and should indicate whether or not specific toxins are commonly involved in plant diseases. A second selective toxin which shows promise for further study has now been found.

The fungus *Periconia circinata* is the causal agent of the 'milo disease' of certain cultivars of *Sorghum vulgare* var. *subglabrescens* (grain sorghum or milo). Other sorghum cultivars are highly resistant. Leukel[3] first identified the causal agent and gave some evidence that a toxin affecting only susceptible plants might be involved in disease development. This interesting possibility was not investigated further.

P. circinata was isolated from a sample of Kansas soil supplied by Mr. W. D. Stegmeier of the Kansas Agricultural Experiment Station. The fungus was grown at approximately 25° C. in a modified Fries No. 3 basal medium[2], supplemented with 0·1 per cent Difco yeast extract. Filtrates were collected from cultures of various ages and tested for selective toxic action against seedlings of *Periconia*-resistant and susceptible sorghums. The seedling assay was patterned after that used for the *Helminthosporium* toxin[2]. Seeds were germinated at 24° C. for 24 hr. between sheets of moist filter paper. Serial dilutions of filtrates were made and 5 ml. of each dilution was placed in a 60 × 15 mm. Petri dish with five germinated seeds. The assay end-point was determined after 48 hr. as the maximum dilution which prevented roots from growing more than 1 cm. long. Control seedlings in water had roots 5 cm. or more in length at 48 hr. Positive assays were obtained from culture filtrates, when *Periconia*-susceptible sorghum seedlings were used as the test object. The highest assay end-point obtained was at a dilution of 1: 3,200. Culture filtrates did not damage seedlings of *Periconia*-resistant sorghum, even when diluted only 1: 10. The peak of toxin content was reached in about twenty-one days in resting culture, whether the fungus was grown in small Erlenmeyer flasks or in large Blake-type bottles, containing 500 ml. of medium. Most cultures grown on a shaker failed to produce toxin.

Filtrates were tested for toxicity against cuttings of *Periconia*-resistant and susceptible sorghum plants. The basal ends of cut shoots were placed in filtrates at dilutions from 1: 50 to 1: 800 and kept at room temperature under artificial light. In all cases the susceptible cuttings were dead and shrivelled within 48 hr., while the resistant cuttings were unaffected and were comparable to controls placed in water. Symptoms of affected cuttings were similar to those of inoculated plants in the greenhouse.

Selectivity of culture filtrates was tested further against seedlings of several sorghum cultivars and non-host plants. The following *Periconia*-resistant sorghums were tried and were not affected by the filtrate: Westland, *SA*-7078, Colby (*Periconia*-resistant selection), Feterita, Texas Blackhull Kafir, Double Dwarf Yellow Milo 38, Atlas Sorgo, and Double Dwarf White Sooner Milo. The susceptible sorghums used, which were all equally sensitive to the filtrate, were Colby, Western Blackhull *X* Day 481004, and Double Dwarf Yellow Milo. Filtrates were tested against the following non-host plants: rye, barley, wheat, oats (Clinton and Park), radish, tomato, crimson clover, carrot, cabbage (Wisconsin Ballhead and Ferry's Hollander), and the fern *Onoclea sensibilis*. There was no indication of toxicity to any of these. Various bacterial and fungal contaminants also were observed growing in toxin-containing solutions from time to time.

Toxin production apparently was correlated with pathogenicity and virulence of the fungus. A total of thirty-two *Periconia* isolates was taken from the soil sample. Eight isolates were pathogenic and produced toxin, while the others were non-pathogenic and did not produce toxin in culture. Four of the pathogenic isolates produced much less toxin in culture than did the other four. Preliminary inoculation experiments gave some indication that the low-toxin producers were less virulent as well.

Some chemical characteristics of the toxin were determined. The toxic activity of culture filtrates passed freely through dialysis membranes, indicating that the toxin has a relatively low molecular weight. Like the wildfire toxin[4] and the *Helminthosporium* toxin[2], the *Periconia* toxin was readily inactivated in alkaline solution, but was stable at acid reactions. Preliminary work indicated that the *Periconia* toxin is more stable than the *Helminthosporium* toxin, since activity was not lost in slightly alkaline solution nor after evaporation of solutions to dryness. These advantages have made it relatively simple to concentrate the material some one-hundredfold and to examine its chemical characteristics. Like the *Helminthosporium* toxin, the *Periconia* toxin appears to be polypeptide in nature. However, the chemical properties of the two toxins are distinctly different as would be expected since there is no biological cross-reactivity between them. The chemical nature and mode of action of this toxin will be investigated further.

Sorghum seeds were kindly supplied by Mr. W. D. Stegmeier of the Kansas Agricultural Experiment Station, Garden City, and by Dr. D. G. Smeltzer of the University of California, Davis.

This investigation was carried out during the tenure of a special fellowship to the senior author from the National Institute of Allergy and Infectious Diseases, United States Public Health Service.

Formation of Phenethyl Alcohol and Tyrosol during Fermentation of a Synthetic Medium lacking Amino-acids

THE fusel oils, or the higher alcohols produced during fermentation, play an important part in the bouquet of wine and the flavour of beer[1]. Since the classical studies of Ehrlich it has been thought that they are produced by degradation of amino-acids, and this point of view has gained considerable support from the recent work of SentheShanmuganathan[2,3]. Nevertheless, Castor and Guymon[4] have pointed out that the concentration of the appropriate amino-acids in grape must is insufficient to explain the level of fusel oils found in the wine, and when Genevois *et al.*[5] found that 1-^{14}C-sodium acetate is incorporated into 3-methylbutanol during fermentation they suggested that the bulk of fusel oil is produced from this or similar intermediates. In considering the formation of fusel oil during beer production it has been pointed out that although the amount of the various amino-acids present in wort and metabolized during fermentation is sufficient to account for the higher alcohols formed by the Ehrlich pathway, this is probably not the only route to these compounds[1].

Harold *et al.*[6] considered that phenethyl alcohol was a key compound for distinguishing between the Ehrlich pathway and that proposed by Genevois, and as they could not verify their earlier identification of this alcohol in beer they favoured the latter mechanism. The presence of phenethyl alcohol in beer, however, has now been well established[7,8] and it was again suggested that although the level of β-phenylalanine present in wort was sufficient to explain the level of this alcohol found in beer, it seemed likely that yeast could produce this alcohol from other metabolites[8]. It is now shown that during fermentation of a synthetic medium lacking amino-acids, yeast produces, in addition to 2-methylpropanol and 2- and 3-methylbutanol previously recognized, both phenethyl alcohol and the non-volatile alcohol, tyrosol, although the corresponding amino-acids, valine, leucine, β-phenylalanine and tyrosine, could not be detected in the final medium.

Eighteen litres of the synthetic medium *FRM*[9] were fermented at 25° using *Saccharomyces carlsbergensis* (N.C.T.C. 396). After 11 days, 84 per cent of the glucose but only 9 per cent of the total nitrogen had been assimilated. The majority of the unassimilated nitrogen was still in a simple form since the same amount of ammonia was found by distilling an aliquot portion with alkali directly as was found after digestion with concentrated sulphuric acid. Two litres of the fermented medium, however, were concentrated by ion-exchange chromatography on 'Amberlite *IR*-120' and the fraction eluted with ammonia was desalted, and examined by two-dimensional chromatography[10]. Only very faint spots corresponding to glycine, glutamic acid, alanine and γ-amino-butyric acid(?) were revealed with ninhydrin while no evidence for valine, leucine, phenylalanine or tyrosine could be seen.

The fermented medium, which contained 1·0 per cent v/v of ethanol and 30 mgm./l. of fusel oil as estimated colorimetrically[11], was distilled and the first 25 per cent of the distillate was collected and extracted continuously with a mixture of ether and light petroleum (b.p. 30–40°) (1:1) for seven days. The extract was dried (potassium carbonate) and the solvent was removed through a column of Dixon gauze spirals from a water-bath at 50°. The resulting extract (151 mgm.) was examined by gas chromatography on dinonyl phthalate at 78° when peaks with retention times corresponding to *n*-propanol (trace) 2-methylpropanol (16 per cent), and 2- and 3-methylbutanol (not separated on this stationary phase) (84 per cent) were observed. The figures in parenthesis correspond to the percentage of the total peak areas. Further examination of this volatile fraction by gas chromatography on 'Apiezon *M*' at 170° revealed the presence of a peak with retention time identical with that of phenethyl alcohol. By use of an internal standard it was calculated that the original concentration of this alcohol in the fermented medium was 1·5 mgm./l.

The residue from the distillation was concentrated to low bulk and extracted with ethanol (3 times). The ethanol solution was evaporated, the residue dissolved in water and the solution continuously extracted by means of ether. When the extract so obtained was examined by paper chromatography in three solvent systems: (1) butanol/acetic acid/water (4:1:1); (2) ethanol/2 *N* ammonia (9:1); (3) 10 per cent aqueous acetic acid, the major component had the same R_F value as authentic tyrosol and gave the same colorimetric reactions with diazotized sulphanilic acid, diazotized *p*-nitroaniline and α-nitroso-β-naphthol. Only in the last solvent system is tyrosol separated from tryptophanol. On these chromatograms diazotized sulphanilic acid revealed a very pale yellow spot with the same R_F as tryptophanol in the fermented medium extract, but it failed to give the characteristic colour change in presence of *p*-dimethylaminobenzaldehyde.

These observations cannot exclude the possibility that the higher alcohols secreted into the medium arise from amino-acids synthesized within the cell. This, however, seems unlikely as the corresponding keto-acids are intermediates common to amino-acid synthesis and the first stage of degradation via the Ehrlich pathway. It is suggested, therefore, that the higher alcohols are by-products of amino-acid and protein synthesis and that the two schemes of Ehrlich and Genevois are not in contradiction but the two extremes of a common mechanism. Thus it is visualized that yeast will assimilate intact amino-acids if available[12]; but if the balance is disturbed it will synthesize the required carbon skeleton, or keto-acid, and deaminate any surplus amino-acid to get the necessary nitrogen. The deaminated amino-acid and any surplus keto-acid intermediate will then be decarboxylated, reduced and secreted into the medium[13].

My thanks are due to Dr. A. H. Cook for his interest and encouragement during this work.

Ultra-Violet Absorption Spectra of Proteins in Deuterium Oxide

TAKASHIMA[1] recently reported that when dissolved in deuterium oxide (D_2O) several proteins exhibited a new absorption band at about 265 mμ, in addition to the well-known absorption bands due to aromatic amino-acid residues[2]. The additional band was also found in a solution of clupein in deuterium oxide; this protein contains no aromatic amino-acid residues, and when pure shows no significant absorption in aqueous solution at wave-lengths longer than 250 mμ. The 265 mμ band was also found in deuterium oxide solutions of six of ten amino-acids examined.

Attempts were made here to confirm the appearance of a new electronic absorption band in deuterium oxide as solvent. Lysozyme, human serum albumin and ovalbumin were examined in 90 per cent (approx.) deuterium oxide, hæmoglobin in 95 per cent (approx.) deuterium oxide, and clupein, insulin, histidine and glycine in 99·8 per cent deuterium oxide. In some cases identical dilutions of a suitable aqueous stock solution were prepared in water and in deuterium oxide and examined side by side; in other experiments the proteins or amino-acids were dissolved directly in deuterium oxide. The solutions were examined with manual and recording spectrophotometers and the positions of the fine-structure bands were located by the moving-plate spectrographic method[3]. Difference spectra of protein solutions of equal concentration in water and in deuterium oxide were also determined on the recording spectrophotometer. In all these experiments no trace of a new absorption band at 265 mμ was observed in the solutions in deuterium oxide, and their spectra did not differ in any significant respect from those of the same solutes in aqueous solution. For hæmoglobin the absorption bands due to the hæm groups were also identical, within experimental error, in water and deuterium oxide. The sample of clupein used was slightly contaminated with nuclear material, giving a broad absorption band ($\lambda_{max.}$ *c.* 265 mμ) of moderate intensity when examined at a concentration of about 10 mgm./ml.; this band was present at the same intensity in both solvents.

The results were communicated to Dr. Takashima and he was able to show that his original findings were erroneous, because of absorbing impurities in the sample of deuterium oxide used. In subsequent observations on amino-acids with saturated side-chains dissolved in pure deuterium oxide, he found selective absorption in the 260–300 mμ region, which was later found to be due to the presence of aromatic impurities, probably tyrosine, in the amino-acid samples.

In view of the agreement which has now been demonstrated between the present observations and Dr. Takashima's subsequent findings, it may be concluded that the use of deuterium oxide as a solvent does not in fact result in the appearance of new bands in the ultra-violet absorption spectra of amino-acids and proteins.

Passive Transfer of Contact Sensitivity to Picryl Chloride in Guinea Pigs, with Subcellular Material

THE possibility of passively transferring delayed hypersensitivity in the guinea pig with viable cells from lymph node, spleen and peritoneal exudate was shown by the work of Landsteiner and Chase[1]. Since then, a number of workers have tried to identify some subcellular material responsible for the transfer. Jeter, Tremaine and Seebohm[2] described the passive transfer of contact sensitivity to 2: 4-dinitrochlorobenzene with sonically disrupted peritoneal exudate cells, but Eisen[3] observed that sonic disruption of lymphoid cells abolished their capacity to transfer contact sensitivity to 2: 4-dinitrofluorobenzene.

The following experiments describe the successful passive transfer with disrupted cells of contact sensitivity to picryl chloride in guinea pigs and the partial separation of the components responsible.

Guinea pigs of the Hartley strain were actively sensitized with picrylated guinea pig red cell stromata in Freund's adjuvant, containing tubercle bacilli, followed three weeks later by successive skin paintings with 4 per cent picryl chloride in absolute alcohol, a technique based on that described by Chase[4]. The donors were killed within two weeks of the last skin sensitization. Spleen and lymph node cell suspensions were prepared as described in ref. 5. Cells were disrupted by freezing and thawing seven times in the presence of deoxyribonuclease[7], or sonically disrupted for 5 min. at 25 kc./sec. Homogenates were prepared in a Potter–Elvehjem-type homogenizer for 3 min. at 3,000 rev./min. in chilled buffered sucrose medium[6] from chopped lymph nodes and spleen cell suspension free from red cells[5]. Cell sap and microsome fractions were prepared from tissue homogenized in the sucrose medium and centrifuged at 5,000*g*. The supernatant was centrifuged in a model *L* Spinco ultracentrifuge at 100,000*g* for 2 hr., and the pellet re-suspended in the sucrose medium.

Cell sap was fractionated by chromatography on N,N-diethylaminoethyl cellulose (DEAE cellulose), by the technique in ref. 8, but using stepwise elution. The DEAE cellulose was buffered to *p*H 7·4 and suspended in 0·01 *M* sodium chloride. The cell sap was diluted to the equivalent of 0·01 *M* sodium chloride before being put on the column. The light absorption of the effluent was examined at 260 and 280 mμ with a Unicam spectrophotometer. The effluent was collected in 10-ml. fractions and three consecutive fractions were pooled for injection into one animal.

Materials were administered intravenously except for the microsome fractions and the eluate from chromatographic fractionation of the cell sap, which were injected intraperitoneally. All recipients were skin-tested with 1 per cent picryl chloride in olive oil immediately after transfusion, and were examined 24–48 hr. later. Reactions were graded according to Chase[4]: + + + +, pink usually very slightly elevated; + + +, pink, but either somewhat pale or macular; + +, pale pink; +, faint pink; ±, many faint pink small spots.

Table 1. COMPARISON OF THE TRANSFER OF PICRYL CHLORIDE HYPERSENSITIVITY BY LIVE CELLS AND DISRUPTED CELLS

(*a*) Disrupted by freezing and thawing

No. of cells	Live cells	Disrupted cells
$1·4 \times 10^9$	+ +	+ +
$7·2 \times 10^8$	+ + +	+ + ±
$5·6 \times 10^8$	+ ±	+ +
$5·6 \times 10^8$	+ + +	+
$6·7 \times 10^8$	+ + +	+ +
	Supernatant after centrifuging at 5,000*g*	
$8·4 \times 10^8$		+ + +
$1·2 \times 10^9$		+ +
$1·2 \times 10^9$		+ +
1×10^9		+ +

(*b*) Sonically disrupted

No. of cells	Live cells	Disrupted cells
$1·5 \times 10^9$	+ +	+ ±
$9·0 \times 10^8$	+ +	+ ±
$6·5 \times 10^8$	+ + +	+ +
$5·0 \times 10^8$	+ + +	+ +

$2·4 \times 10^9$	+ ±	+ + +
$1·8 \times 10^9$	±	+ + +
$1·25 \times 10^9$	−	+ + ±

All reactions read 24–48 hr. after transfer.

Table 2. TRANSFER OF PICRYL CHLORIDE HYPERSENSITIVITY WITH CELLS DISRUPTED BY HOMOGENIZATION. COMPARISON OF ACTIVITY IN CELL SAP AND MICROSOME FRACTIONS

Cell sap	Microsomes
+ +	+ + ±
+ +	+ +
+ +	+ +
+ + ±	+ +
+ + +	+ + ±
+ + +	+ + +
+ + +	+ +
+ + ±	+ +

All samples from lymph nodes and spleens of two donors. All reactions read 24–48 hr. after transfer.

A comparison of the transfer of contact sensitivity by live cells and cells disrupted by freezing and thawing or sonically disrupted is shown in Table 1. There was a marked fall in the activity of the preparation on disruption. Nevertheless, considerable activity remained in the supernatant after centrifugation at 5,000*g*. In the case of sonically disrupted cells, the 5,000*g* supernatant contained almost all the activity. On fractionation of the supernatant, after homogenization in sucrose medium, by centrifugation at 100,000 *g*, activity was found in both the cell sap and microsome fractions (Table 2). The activity of the cell sap survived dialysis overnight at 4° C. Preliminary experiments have shown that the active material in the cell sap can be partially separated by chromatography, being retarded on DEAE cellulose at 0·01 *M* sodium chloride, whereas most of the protein (as judged by the absorbance ratio 260/280 mμ) is completely retained at this ionic strength.

I wish to thank Dr. H. J. Rapp for advice, and Mr. G. Kenny for technical assistance.

PHYSIOLOGY

Inhibition by Physostigmine of the Increase of Oxygen Consumption induced by Potassium in Muscle

THE immersion of frog muscle in Ringer solution, with a high potassium content, is known to cause a decrease in the resting potential of the fibres accompanied by a large increase in oxygen consumption and heat production of long duration; no mechanical change of muscle is observed in these conditions. A possible cause of this effect was discussed by Hill and Howarth[1], and a hypothesis was suggested according to which the depolarization produced by potassium releases the catabolic processes normally accompanying contraction of muscle. Nevertheless, the whole mechanism is still very obscure.

The experiments to be reported here suggest that some special energy-consuming system, different from the main energy-producing metabolic pathways, is involved in the process. The experiments were carried out on sartorius muscles of the frog *Rana temporaria* during February–April. The muscles were used within 30 min. after dissection. Oxygen consumption was measured at a temperature of 22° C. in a Fenn respirometer. Fig. 1 shows that the increase of oxygen consumption in 18 m*M* potassium Ringer is practically completely inhibited by the addition of 10^{-4} *M* physostigmine. This inhibition is not caused by blocking the energy-producing metabolic system (respiration or glycolysis), because subsequent addition of 3×10^{-5} *M* 2,4-dinitrophenol to the same experimental vessel increases the oxygen consumption again to the same high level as is observed with muscles not treated with physostigmine.

Because physostigmine inhibits cholinesterases in concentrations of about 10^{-6} *M*, different lower concentrations of physostigmine were tested (Table 1). The concentration of 10^{-5} *M* was still effective, but to obtain a pronounced effect it was necessary to soak the muscle for 90 min. in 10^{-5} *M* physostigmine before adding 18 m*M* potassium Ringer solution. This we believe to be due to the slow penetration of physostigmine into the muscle cells. The concentrations inhibiting the potassium effect are distinctly higher than those required for inhibition of cholinesterase in homogenates; however, the conditions in intact cells and in homogenate need not be strictly comparable.

Fenn[2] has reported that sucrose in isotonic concentration causes an increase of oxygen consumption similar to that produced by 18 m*M* potassium[2], but we have found that, unlike the increase induced by potassium, this increase is not inhibited by physostigmine (Table 1). The results suggest that these two processes are due to different mechanisms.

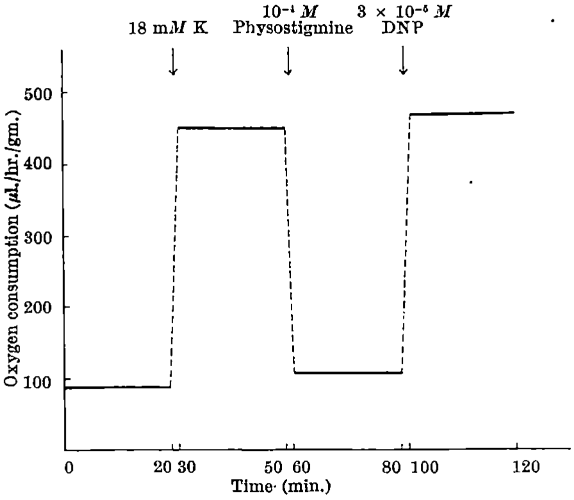

Fig. 1. Influence of 18 m*M* potassium Ringer solution, 10^{-4} *M* physostigmine and 3×10^{-5} *M* 2,4-dinitrophenol on the oxygen consumption of frog's sartorius muscle measured successively in the same experiment. The first part of the graph gives the resting value in normal Ringer

Physostigmine is known to be a potent inhibitor of both cholinesterase and pseudocholinesterase; however, with respect to the well-known role of cholinesterase in various excitation processes, it may be assumed that the inhibitory effect of physostigmine is due to its action on true cholinesterase. It is suggested that the acetylcholine cycle proposed by Nachmansohn[3] for regulation of the permeability of nerve membrane may be activated by high external concentration of potassium. The cyclic splitting and re-synthesis of acetylcholine might be the energy-consuming process which brings about the increase of metabolism.

The possibility that the high rate of metabolism, due to application of potassium, may be associated with active transport of ions was rejected by Hill and Howarth[1]. In agreement with their view, we have found that this metabolic increase is not influenced by ouabain in concentrations inhibiting active transport. The findings of Van der Kloot[4] that physostigmine influences the exchange of ions in frog muscle is not necessarily in conflict with our results, because the effects reported in his paper could be due to the change of permeability. It appears improbable that a high concentration of potassium ions acts by uncoupling the oxidative phosphorylation[5], because the muscle after inhibition by physostigmine is still normally sensitive to 2,4-dinitrophenol.

Table 1. EFFECT OF DIFFERENT SUBSTANCES ON THE OXYGEN CONSUMPTION OF THE FROG'S SARTORIUS MUSCLE. DURATION OF EVERY EXPERIMENT WAS 30 MIN.

Treatment	No. of experiments	Oxygen consumption (μl./hr./gm.)
Normal Ringer solution	6	86 ± 19
Ringer with 18 m*M* potassium	6	437 ± 82
+ 10^{-4} *M* physostigmine	6	112 ± 31
+ 10^{-5} *M* physostigmine	6	226 ± 75
+ 10^{-6} *M* physostigmine	3	441 ± 134
Ringer with 18 m*M* potassium + 10^{-4} *M* physostigmine + 3×10^{-5} *M* 2,4-dinitrophenol	7	483 ± 136
Isotonic sucrose	5	456 ± 108
Isotonic sucrose + 10^{-3} *M* physostigmine	6	427 ± 110

The possibility cannot be neglected, however, that physostigmine may act as membrane stabilizer[6], decreasing the sensitivity of the membrane to the depolarizing action of potassium.

We are indebted to Dr. V. Kubišta for helpful advice and discussion during this work.

Response of the Labellar Hairs of the Blowfly, *Phormia regina* Meigen, to Protein

STRANGWAYS-DIXON[1] has shown that the blowfly *Calliphora* has a cyclic preference for protein. Females ingest relatively more protein than carbohydrate during the early stages of egg growth, but relatively more carbohydrate during yolk formation. They will not reproduce without a protein diet[2].

Receptors responsive to protein have not yet been described. The work presented here was done with another blowfly, *Phormia regina* Meigen, and shows that the chemosensory hairs of the labellum can act as protein receptors. Electro-physiological studies were made on the hairs by recording from the tip in the manner of Hodgson, Lettvin and Roeder[3], and by side-wall recording[4].

There are at least three sizes of chemosensory hairs on the labellum : large hairs situated peripherally, intermediate hairs inside these and very small hairs situated centrally and between the other hairs. There may be a further size of hair slightly larger than the small hairs. Most workers appear to have studied the large peripheral hairs.

When stimulated with hæmoglobin solution (6 gm. in 100 ml. water) or brain-heart infusion (10 gm. in 100 ml. water), the large hairs give records in which two sizes of spike are present (see Fig. 1*A*). Hæmoglobin typically causes the large spike to fire at a frequency of 1–5/sec., whereas the small spike fires at 8–13/sec. Both fire somewhat irregularly. There is some indication that the large spike becomes adapted more quickly than the small spike. Most of the large hairs respond in this fashion, but some at least of the intermediate hairs give a response in which only the smaller spike fires. On the other hand, some of the small hairs give a response in which only the larger spike is firing. It cannot yet be said whether all the intermediate and small hairs give these distinctive responses.

Male *Phormia* have a largely carbohydrate diet. However, electrically their labellar hairs appear to respond identically to those of females towards protein solutions. The virtual absence of a behavioural response to protein must be due not to a difference in the peripheral mechanism but to a different central interpretation of afferent input.

Thus, two nerve fibres seem to be stimulated by protein solutions. The fibre giving the smaller spike has the characteristics—(1) longer time course and (2) greater variability of height of spike when recording from the tip—of the fibre which is now known to be responsive only to water[5]. It fires together with the fibre responsive to salts (*L* fibre) when weak solutions of salt stimulate the hair and it fires together with the fibre responsive to sugar (*S* fibre) when solutions of sugar stimulate the hair (see Fig. 1*B*). In fact, when a mixture of weak salt and sugar solutions stimulates the hair, spikes of three sizes are usually detectable in tip records. These may only become apparent on statistical analysis, as in Fig. 2. The three sizes of spike represent the *L*, *S* and *W*(ater) fibres.

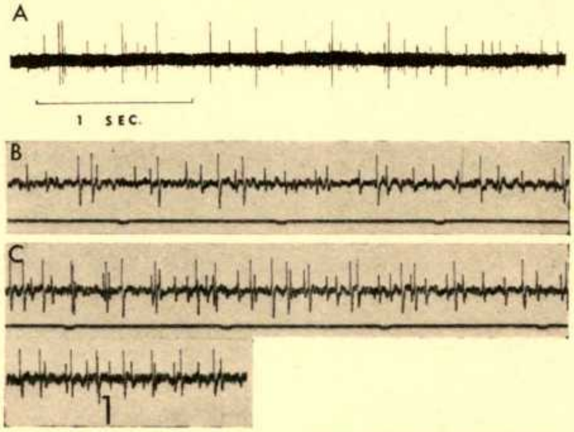

Fig. 1. *A*. Tip recording from a large labellar hair stimulated by hæmoglobin solution. A small and a large spike are present. (Tracing of original record.) *B*, Side-wall recording from a large labellar hair stimulated by 1 *M* fructose solution. Time base, 200 msec. *C*, Side-wall recording from a large labellar hair stimulated by a mixture of 50 per cent 0·1 *M* sucrose and 50 per cent hæmoglobin solution. The pointer indicates the possible firing of one large spike in the refractory period of another. Time base, 200 msec.

Experiments are in progress to determine whether the large spike firing to protein solutions is one of the four nerve fibres known to be present in the chemosensory hairs or a further one. Dethier[6] showed that two fibres, the *L* and the *S*, ascend the shaft of the hair, and a mechanoreceptor fibre terminates somewhere in the socket region. Larsen (personal communication) has since shown that a third fibre ascends the shaft and this is presumably the *W* fibre. Since protein produces an acceptance response, it is unlikely that the protein stimulates the *L* fibre which mediates behavioural rejection. Side-wall recording when stimulating with a mixture of 50 per cent hæmoglobin and 50 per cent 0·1 *M* sucrose gives records which, though difficult to interpret, may indicate that protein has a fibre specific to itself and separate from the *S* fibre. With side-wall recording, the sizes of spikes are (for the

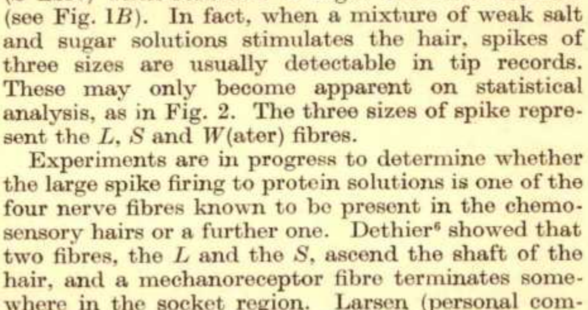

Fig. 2. Histogram showing the frequency distribution of size of spikes obtained from records where a large labellar hair was stimulated with a mixture of 50 per cent 0·1 *M* sodium chloride and 50 per cent 0·1 *M* sucrose solution. The largest spike is the *L* fibre, the smallest the *W* fibre and the middle spike the *S* fibre. (Tip recording)

L and *S* spikes) often identical. In Fig. 1*C* the occurrence of firing by one fibre in or very close to the refractory period of another indicates that three spikes may be present. One of these spikes must be the *S* fibre, another the *W* fibre, and if a third is present it must be responding specifically to the protein. This evidence is tentative, but it is significant that J. R. Larsen (personal communication) has histological evidence of some hairs with four fibres ascending the shaft. These could be the *L*, *S*, *W* and a protein fibre.

Changes in the Membrane during Recurrent Disinhibition of Spinal Motoneurons

IT has been proposed on the basis of pharmacological evidence that recurrent facilitation of spinal motoneurones in the cat is actually a removal of background inhibition, that is, a disinhibition[1]. The results of initial intracellular investigation have been consistent with this hypothesis[2]. It is the purpose of this communication to present direct evidence which lends strong support to the disinhibition hypothesis.

All experiments have been performed on cats the spinal cord of which had been transected at the atlanto-occipital membrane. The carotid arteries were tied, the vertebral arteries clamped, and the preparation was immobilized by intravenous injections of 'Flaxedil' (gallamine triethiodide, American Cyanamid Co.). The experimental arrangement has been described previously[3]. Intracellular recording was by means of glass micropipettes filled with 2·7 *M* potassium chloride or 2 *M* potassium citrate. By utilizing a bridge circuit similar to that used by Frank and Fuortes[4], it was possible to use the same micro-electrode for recording from and for passing current through the cell.

As a result of a recurrent facilitatory volley, a small depolarization (recurrent facilitatory potential) frequently develops in a conditioned motoneurone[2]. Such a recurrent facilitatory potential could be due to either of two events. First, it could be due to an excitatory process such as that which produces the usual excitatory post-synaptic potential. Second, it could be due to removal of inhibition. If background inhibitory activity is one of the factors determining the level of resting potential, which in the motoneurone is less negative than is the inhibitory equilibrium potential[5], then any decrease in the background inhibitory activity would appear as a depolarization. A clear-cut distinction between an excitatory depolarization, accompanied by an increase in conductance, and a depolarization due to removal of inhibition and accompanied by a decrease in conductance, can be drawn by changing the level of membrane potential. An excitatory post-synaptic potential (EPSP) would be decreased by depolarization, while its amplitude usually would not be changed significantly by hyperpolarization[6]. A different situation would prevail with a disinhibitory depolarization. Decreasing the membrane potential would move it further from inhibitory equilibrium, and increase both the effect of background inhibition on the membrane potential[5] and the subsequent recurrent facilitatory potential. Hyperpolarization would cause an opposite effect. Moving the membrane potential closer to the inhibitory equilibrium would decrease the effect of background inhibition on the membrane potential[5] and the recurrent facilitatory potential. If the membrane potential is shifted to the other side of inhibitory equilibrium, background inhibition will cause depolarization of the cell and release from inhibition will cause hyperpolarization; that is, the recurrent facilitatory potential will be reversed. Precisely such a reversal has been obtained in the present experiments.

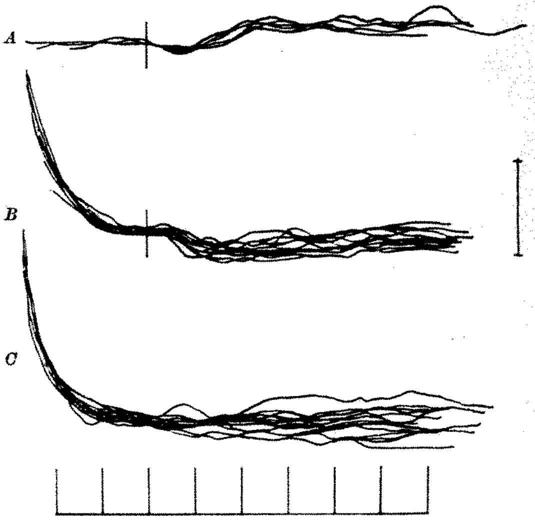

Fig. 1. Effect of hyperpolarizing pulses on recurrent facilitatory potential. The potentials shown in this figure were traced from a number of single frames. Conditioning stimulus delivered at artefact. *A*, Recurrent facilitatory potential alone; *B*, accompanied by hyperpolarizing pulse; *C*, hyperpolarizing pulse alone. Voltage calibration, 10 mV.; time, 10 msec.

Fig. 1 shows the effect of hyperpolarizing pulses on the recurrent facilitatory potential recorded with a 13-megohm potassium chloride electrode in a deep peroneal motoneurone. Superimposed tracings of control recurrent facilitatory potentials are shown in Fig. 1*A*. Such controls were interspersed among other frames, illustrated in Fig. 1*B*, which show the effect of pulses of hyperpolarizing current 100 msec. in duration and $1·2 \times 10^{-8}$ amp. in magnitude on the recurrent facilitatory potential (the latter has been delayed sufficiently so as not to fall on that part of the base-line distorted by the bridge transient). It is clear that the polarity of the recurrent facilitatory potential has been reversed. Fig 1*C* is a control which shows that aside from the bridge transient the base-line, with the current pulse on but conditioning stimulus off, is quite flat.

Similar results have been obtained in a quadriceps cell in which the recurrent facilitatory potential was reversed by a current pulse which also reversed a recurrent inhibitory post-synaptic potential (IPSP). In several other cells, both quadriceps and deep peroneal, electrode polarization negated attempts to reverse the recurrent facilitatory potential. However, even under such conditions the recurrent facilitatory potential was consistently decreased by hyperpolarizing pulses or increased by depolarizing pulses.

These results are inconsistent with the possibility that the recurrent facilitatory potential is produced by a mechanism similar to that which produces the excitatory post-synaptic potential, and completely in accord with the hypothesis that the recurrent facilitatory potential is produced by removal of inhibition. This direct evidence of the nature of the membrane changes confirms the interpretation of the previous pharmacological[1] and intracellular[2] experiments. Disinhibition, therefore, must be considered as a mechanism which contributes, under physiological conditions, to the integrative action of the central nervous system. Parenthetically, these results demonstrate that in the spinal cat both extensor and flexor motoneurones of hind limb muscles are under the influence of tonic inhibitory activity.

This investigation was supported in part by grant *B*–2619 from the Institute of Neurological Diseases and Blindness, U.S. Public Health Service.

Stimulation of the Heart of the Spinal Dog by Phenoxybenzamine

ANTISYMPATHOMIMETIC drugs have been shown to interfere with the inactivation of the sympathetic transmitter substance. Brown and Gillespie reported that the amount of noradrenaline appearing in the splenic venous blood following sympathetic stimulation at frequencies below 30/sec. is increased by phenoxybenzamine or dibenamine, and these authors concluded that the mechanism for the destruction of noradrenaline at the nerve endings is linked to the receptor for this substance and can be inactivated with them[1]. Brown, Davies and Gillespie found that large amounts of noradrenaline appear in the venous blood from both colon and small intestine if the sympathetic nerves were stimulated following the administration of phenoxybenzamine[2]. Millar *et al.* showed that phenoxybenzamine enhances the rise in plasma noradrenaline during hæmorrhagic hypotension in adrenalectomized dogs[3]. Benfey *et al.* found that the urinary excretion of noradrenaline following ganglionic stimulation by acetylcholine is increased by phenoxybenzamine[4]. Hukovic showed that phenoxybenzamine augments the response to stimulation of the atrium of the heart isolated with its sympathetic nerves[5]. Benfey *et al.* reported that phenoxybenzamine elevates the urinary recovery of infused noradrenaline[6]. Martin *et al.* found that chlorpromazine can enhance and prolong the vasoconstrictor and chronotropic actions of adrenaline and noradrenaline[7].

It appears that antisympathomimetic drugs can also release the sympathetic transmitter substance. In the present experiments dogs in pentobarbitone anæsthesia were subjected to a cord transection between C_1 and C_2 and to a bilateral vagotomy. The contractile force of the exposed heart was recorded by a Cushny myocardiograph, the blood pressure was measured from the carotid artery, and artificial respiration was given. Fig. 1 shows that the intravenous injection of 10 mgm./kgm. of phenoxybenzamine (dibenzyline hydrochloride, Smith, Kline and French) briefly depressed and then increased the force of contraction of the heart. The increase in contractility was associated with a rise in heart-rate (from 120 to 180/min.), and there was a small hypertensive effect. 50 min. later, when the heart-rate had dropped slightly, the intravenous injection of 0·5 mgm./kgm. of reserpine ('Serpasil', Ciba) increased the heart-rate further (from 170 to 230/min.). The ganglion-blocking drug pentolinium was originally used in repeated doses of 2·5 mgm./kgm. to counteract an excessive rise in blood pressure that was observed during the manipulation of the spinal cord. In the absence of pentolinium the results were similar, but phenoxybenzamine stimulated cardiac contractility immediately and the chronotropic effect was somewhat greater.

Since it has been found before that in anæsthesia phenoxybenzamine has hypertensive and positive inotropic and chronotropic actions following ganglion-blocking drugs or atropine even in dogs injected with 20 mgm./kgm. of phenoxybenzamine the day before, but not in animals given reserpine or guanethidine 24 hr. earlier[8], it is concluded that the drug releases catecholamines in small amounts. It has also been reported earlier that phenoxybenzamine increases the plasma concentration and urinary excretion of adrenaline and noradrenaline which is associated with a fall in blood pressure[3,4]. However, no rise in the urinary output of the catecholamines was detected when ganglion-blocking drugs or vasopressin eliminated a reflex activation of sympathetic fibres by hypotension[4,6]. Chlorpromazine has recently been

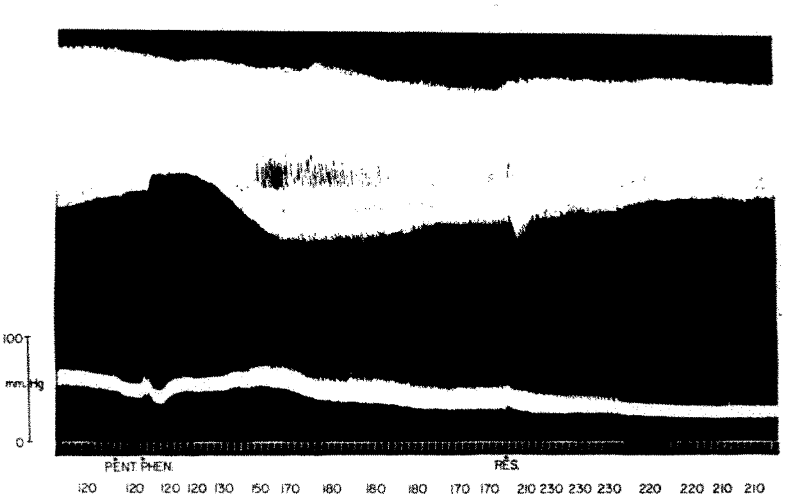

Fig. 1. Cardiac contractility, blood pressure and heart-rate of a dog (10·0 kgm.) subjected to cervical spinal cord transection and vagotomy. Time in minutes. PENT, 2·5 mgm./kgm. pentolinium; PHEN. 10 mgm./kgm. phenoxybenzamine; RES, 0·5 mgm./kgm. reserpine injected intravenously

shown to have hypertensive and positive chronotropic actions in the spinal vagotomized cat[7].

It is suggested that the antisympathomimetic effect (adrenergic blockade) involves both an impaired inactivation and a release of the sympathetic transmitter substance.

HÆMATOLOGY

Large Lymphocytes and the Simonsen Phenomenon

When blood cells from an adult fowl are inoculated on the chorioallantoic membrane of the 12-day-chick embryo, easily visible opaque foci are produced[1,2]. This reaction is thought to be similar to the induction of splenomegaly following intravenous inoculation of adult fowl blood into the chick embryo[3]. The cells in blood responsible for this latter action have been found to be the lymphocytes[4]. Fowls are typical of the avian family in having a high proportion of circulating large lymphocytes, usually about 10 per cent, and, as autoradiographic investigations[5,6] have shown that large lymphocytes and not small can synthesize deoxyribonucleic acid and proliferate, an investigation was made to determine the type of lymphocyte responsible for the induction of lesions on the chorioallantoic membrane. Blood from a group of 25 random fowls was titrated on the chorioallantoic membrane, the number of small and of large lymphocytes in the inoculated blood having been determined. A highly significant correlation (0·1 per cent in Student's t test) of the number of large lymphocytes in the inoculum with the median focal count was demonstrated. The correlation of small lymphocytes with the focal count was not significant ($>$ 5 per cent). In repeated titrations of individual fowls, the focal count was also shown to depend on the number of large lymphocytes in the inoculum and to be quite independent of the number of small lymphocytes.

Quantitative determinations of the number of large lymphocytes required to produce foci were carried out. This was found to be dependent on the number of cells inoculated. Over the average range of inoculum used, about 2,000 large lymphocytes were required to produce one focus. As the inoculum was progressively diluted, more large lymphocytes seemed to be able to produce foci, and as few as 40 were shown to be capable of this action.

As the large lymphocytes were now satisfactorily identified as the competent cells in this phenomenon, the competence of large lymphocytes from other organs was studied, namely spleen and thymus. Thymic large lymphocytes were shown to be virtually incompetent in the production of foci, the small number of foci being easily accounted for by a 2 per cent contamination with blood large lymphocytes, in accordance with Terasaki's results[4]. The relative competence of the large lymphocytes of blood and spleen was assessed by: (1) direct titration on the chorioallantoic membrane; (2) the number of cells required to produce a maximal increase in spleen weight after intravenous inoculation; (3) by passaging cell suspensions of these enlarged embryonic spleens on to further chorioallantoic membranes, and establishing the number of passage cells required to produce foci. By all three criteria, the large lymphocytes from spleen were demonstrated to have about 20 per cent the competence of the large lymphocytes in blood.

This work was supported by research grants from the National Health and Medical Research Council, Canberra, and we are grateful to Sir Macfarlane Burnet for helpful discussions during the course of the investigations.

Influence of Serum Factors on the Species-specificity of Tissue Thromboplastin

It is well recognized that a difference in species may influence the time of clotting of recalcified plasma in the presence of tissue extract. Using Quick's one-stage procedure, tissue extract will give a shorter clotting-time with homologous plasma than with plasma from a different vertebrate. Mann and Hurn[1] demonstrated that the specificity of a tissue extract could be eliminated by incubating it with a small amount of homologous serum in the presence of calcium ions before adding the heterologous test plasma. At this time, factor VII (cothromboplastin, S.P.C.A., proconvertin) and factor IX (Christmas factor, P.T.C.) were the only clotting factors known to be present in serum, and as factor IX plays no part in the conversion of prothrombin to thrombin by tissue thromboplastin, Mann and Hurn concluded that the species-specificity was eliminated by the presence of homologous factor VII.

It is now recognized that normal mammalian serum contains another factor which plays a part in the activation of prothrombin, namely, factor X (Stuart Prower factor). The experiments of Mann and Hurn have been extended in the light of this knowledge in order to determine whether the so-called 'cothromboplastin effect' is due to factor VII alone, or whether factor X also influences the reaction.

The tests were carried out in plasma from the South African clawed toad, *Xenopus laevis*, using human brain thromboplastin. Toad plasma was obtained from animals anæsthetized by immersion in 2 per cent urethane solution for 10–15 min. The heart was exposed and, holding the animal in a dorso-ventral position, the ventricle was caused to protrude by pressure on the dorsal surface behind the head. The pericardium was removed and the ventricle punctured with a sharp blade, allowing the blood to drop into a graduated polythene tube containing 3·8 per cent trisodium citrate. Nine volumes of blood were collected into one volume of citrate solution. The blood from six toads was pooled to make a single specimen.

Human brain thromboplastin was prepared by the method of Hjort[2]. The dilution was adjusted to give a satisfactory one-stage thromboplastin time with normal human plasma. Human blood was collected into 3·8 per cent trisodium citrate in the proportion of nine volumes of blood to one of citrate, a siliconed syringe being used. Platelet-poor plasma was obtained from citrated blood by centrifuging for 20 min. in an International clinical centrifuge, model *CL*, with a 7 in. head. Serum free from prothrombin and thrombin was prepared by incubating clotted blood for 5 hr. at 37° C. in a glass container, and was stored after separation at $-20°$ C. for up to one week. Serum free from factor VII was obtained from a patient with a pure congenital deficiency in factor VII. Serum free from factor X was obtained from a patient with a pure deficiency in factor X. Serum from a patient under treatment with phenylindanedrone (phenindione, B.P.) was also tested; this contained 1 per cent of factor VII and 3 per cent of factor X. In all the above sera factor VII was assayed by the method of Dische[3] and factor X by the method of Bachmann *et al.*[4].

All sera were diluted 1 in 10 with normal saline. For the test 0·2 ml. brain thromboplastin was incubated at 37° C. with 0·1 ml. diluted serum and 0·2 ml. 0·025 *M* calcium chloride for 3 min. A stop-watch was started on the addition of 0·2 ml. of plasma, and the clotting-time recorded. The results are shown in Table 1.

Table 1. EFFECT OF DILUTE HOMOLOGOUS SERA ON THE REACTIVITY OF THROMBOPLASTIN AND PLASMA

Thromboplastin	Reagent added	Plasma	Clotting time (sec.)
Human	Saline	Human	12·5
		Toad	61
	Normal human serum 1 in 10	Human	12·5
		Toad	13
	Factor VII deficient human serum 1 in 10	Toad	25
	Factor X deficient human serum 1 in 10	Toad	29
	Phenindione serum 1 in 10	Toad	58

These results indicated that the species-specificity of tissue thromboplastin is dependent on the presence of both factor VII and factor X.

PATHOLOGY

Induction of Cancer in Suckled and Unsuckled Female Rats

SPONTANEOUS mammary carcinomas are a very rare event in female Sprague–Dawley rats[1], but this type of tumour can be produced easily and rapidly by repeated administration of 3-methylcholanthrene (3-MC) given by stomach tube[2]. The neoplasias are more easily produced in young than in old rats and regress under appropriate hormonal modifications. Ovariectomy, hypophysectomy and critical amounts of œstrogens and gonadotropins are effective means of inhibiting neoplastic proliferations[2,3]. Tumours of this kind are known as hormone-dependent. The hormonal conditions during pregnancy are of great significance in growth of tumour. It has been shown that rat mammary tumours appear more rapidly when 3-MC feeding is followed by pregnancy and the incidence of mammary cancers is reduced if the carcinogen is given during pregnancy. No induction of tumours is observed by giving 3-MC during lactation[4,5]. Also, in mice the influence of pregnancy and lactation on 3-MC induction of mammary tumour has been stressed[6].

The following experiment has been aimed to determine whether a previous life-history of different events (for example, pregnancy, lactation) modifies the subsequent susceptibility of rat mammary tissue to 3-MC tumour induction.

3-MC, 10 mgm. in 1 c.c. sesame oil, was administered by gastric tube 6 days a week for 50 days to female Sprague–Dawley rats. Two groups of rats, intact and ovariectomized, received the first administration at 50 days of age. Three other groups, which underwent treatment at age 310–320 days, were (*a*) virgin females, (*b*) females which had previously reared four litters, (*c*) females which had previously been four times pregnant but never suckled. Breeding had begun at 80 days; henceforth, matings occurred two weeks after weaning of the litters at 21 days. Lactating mothers nursed a total of 20–30 young each. Non-lactating mothers rested about 35 days before being mated again. Breeding was completed before treatment with 3-MC began. Diet (18 per cent protein ration plus tap water *ad libitum*) and environmental conditions were alike for all animals during the experiments. The rats were inspected daily for palpable tumours and observed for 120 days from the last administration of 3-MC. Histological sections were stained with hæmatoxylin–eosin.

3-MC, 10 mgm., given by mouth six times weekly for 50 days to intact 50-day-old rats invariably

Table 1. INFLUENCE OF DIFFERENT HORMONAL CONDITIONS ON INDUCTION OF MAMMARY TUMOUR BY 3-MC IN YOUNG AND OLD FEMALE RATS

Category	No. of rats	Toxic deaths	Rats with tumours	Tumour appearance (days)		
				Range	Median	Mean
Young virgin females	8	—	8/8	43–72	51	52·83 ± 3·50†
Young ovariectomized*	11	4	5/7	53–96	56	70·40 ± 9·50
Old virgin females	8	3	3/5	42–79	—	—
Suckled mothers	8	2	2/6	48–71	—	—
Unsuckled mother†	9	8	0/1	—	—	—

* Ovariectomized at age 42 days † Standard error.

elicited multiple mammary tumours (Table 1). Also it produced no toxic deaths. Unsuckled mothers, subjected to the same treatment, died before tumours could be palpated. Suckled mothers tolerated the carcinogen fairly well and two of six developed tumours. Young, ovariectomized and old, virgin rats had similar mortality-rates. Three rats out of five survivors showed tumours in intact old females. While incidence of tumours was variable, the time for appearance of tumours after 3-MC treatment showed no variation. The only exception was registered for ovariectomized rats, in which induction of tumours was delayed.

Histologically, all observed tumours were recognizable as adenocarcinomas. The only variant was observed in the castrated females, the tumours of which exhibited a sclerotic and cystic appearance. Gland atrophy with occasional proliferating areas featured in the mammary tissue of old rats. The mammary glands of young intact and ovariectomized rats displayed epithelial proliferations and atrophy, respectively.

The experiment described shows that intolerance to 3-MC affects ovariectomized young and unmated old females, while surprisingly, the carcinogen was lethal to all the unsuckled mothers, except one. Despite the high mortality, the results suggest that the breast of rats which lactated and that of unbred old rats is less susceptible to 3-MC mammary cancer induction than that of young unbred or ovariectomized rats. Age or different events in the past reproductive activity of female rats have no influence on the rate of tumour appearance after 3-MC treatment. It seems that mammary epithelium (though atrophic) of old rats retains different reacting capacity to a carcinogenic stimulus (3-MC) in relation to its previous functional activity.

Amino-Acid Composition of Serum Mucoprotein in Rheumatic Fever

INTEREST in serum mucoprotein tyrosine levels as one of the most sensitive, albeit non-specific, gauges of the disease process in cases of rheumatic fever suggested the possibility that there might be differences in the amino-acid composition of the serum mucoprotein at a time when serum-levels were significantly elevated.

Mucoproteins from five cases of active rheumatic fever whose mean serum mucoprotein tyrosine level was 14·6 (11·9–16·1) mgm./100 ml. and from three normal children of comparable age and with normal serum mucoprotein tyrosine levels of 3·9 (3·2–4·3) mgm./100 ml. were separated from other serum proteins by their solubility in 1·2 *M* perchloric acid. After precipitation with 5 per cent phosphotungstic acid the mucoprotein was washed with ethanol, dissolved in a minimum of 0·1 *N* sodium hydroxide, and finally hydrolysed *in vacuo* in 6 *N* hydrochloric acid for 22 hr. at 110° C.

Analysis of the acid hydrolysate for amino-acids was carried out on a Beckman/Spinco continuous flow column chromatography apparatus using 150-cm. and 50-cm. columns with standard buffers and temperatures. The mean of the analyses for normal people and for the rheumatic fever cases are shown in Table 1. To facilitate comparison the results are expressed as moles/mole of alanine.

Table 1

	Normal (moles/mole of alanine)	Rheumatic fever (moles/mole of alanine)
Aspartic acid	1·46	1·66
Threonine	1·09	1·25
Serine	0·66	0·82
Glutamic acid	2·07	2·20
Proline	1·00	0·87
Glycine	0·91	0·94
Alanine	1·00	1·00
Valine	0·87	0·84
Methionine	0·16	0·14
*iso*Leucine	0·62	0·71
Leucine	1·23	1·34
Tyrosine	0·57	0·66
Phenylalanine	0·72	0·76
Lysine	1·19	1·15
Histidine	0·35	0·35
Ammonia	3·98	3·32
Arginine	0·57	0·63

Values for tryptophan, glucosamine, and cystine are affected by acid hydrolysis and are not given. The figures suggest no difference in amino-acid composition between serum mucoproteins in health and during acute rheumatic fever.

Effect of Calf Thymus Histone on Rats bearing Transplantable Acute Myeloid Leukæmia

THE bactericidal activity and the cytotoxic effect of basic proteins, protamines and histones have been investigated by different workers. However, the cytostatic effect of histones on tumour cells *in vitro*[1–3] and *in vivo*[4] deserves more attention. Do histones possess a specific growth regulatory activity as was suggested by Zbarskii[4], are they gene inhibitors as Stedman has outlined in his theory[5], or is the inhibitory action of histones on tumours due only to their high toxicity in the experimented animals ?

According to recent work[1], histones and protamines as very basic proteins are incorporated rapidly into the cells *in vitro*. The presence of such positively charged proteins within the cells produces changes in their structure and metabolism, with the resulting destruction of the treated cells.

In an effort to estimate the cytostatic effect of histones, rats bearing acute myeloid leukæmia[6] were treated with calf thymus histone prepared according to the method described by Butler *et al.*[7].

The acute myeloid leukæmia was transplanted into adult 150-gm. albino rats by intravenous injection of the homogenate from leukæmic rat liver, which was heavily infiltrated with leukæmic leucocytes. Histone was administered in 5 per cent solution in physiological saline in 500 mgm./kgm. doses. The first injection of histone was intraperitoneal and the subsequent ones, if any, were placed in the dorsal subcutis. Three experimental and one control group of rats were used.

In the first group the animals were injected 1 hr. before transplantation of leukæmia. In the second group, histone was injected 3 hr. after transplantation and then on the third and fifth day. The third group was treated with histone on the second and fourth day following transplantation.

All animals in the control group were injected with 1·5 ml. of physiological saline 3 hr. after transplantation, and then on each alternate day following the transplantation.

Sections of liver and spleen of all animals which died during the experiment were examined histologically for the presence of leukæmic infiltrates using the method of direct imprints.

Table 1

Group No.	No. of injected animals	Animals died due to toxicity of histone	Animals died of leukæmia	No. of survivors
I	10	1	9	0
II	15	2	11	2
III	20	4	14	2
Controls	10	0	6	4

The toxicity of calf thymus histone in rats depends on the manner of administration. Thus the LD_{50} was 50 mgm./kgm. for intravenous, 700 mgm./kgm. for intraperitoneal and 1,500 mgm./kgm. for subcutaneous (dorsal subcutis) administration. Therefore for better tolerance all injections following the first intraperitoneal one were subcutaneous.

It follows from the results in Table 1 that the calf thymus histone has no cytostatic effect on rats bearing acute transplantable leukæmia. On the other hand, probably as a result of toxicity, the average survival of all animals treated with histone was less than 30–40 per cent of controls and of transplantation experiments[6].

IMMUNOLOGY

A Relation between the Reactivity of Human Red Cells to Antiglobulin Tests and their Surface Structure

SEVERAL authors[1] have suggested that changes in the immunological reactivity of a cell may be correlated with changes in its surface structure. We present evidence here that human red cells giving a positive antiglobulin reaction show changes in their surfaces demonstrable with the electron microscope.

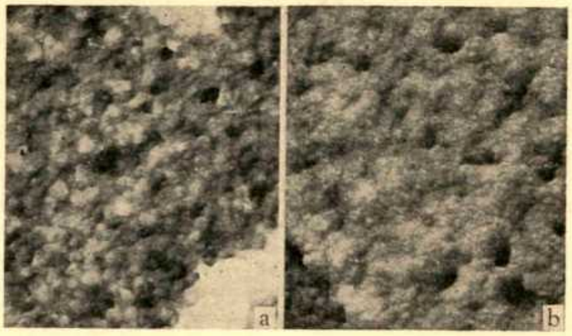

Fig. 1. Surface of (*a*) hæmolysed norma lerythrocyte; (*b*) surface of hæmolysed sensitized erythrocyte from same blood sample. (× 40,000)

Rh(D) positive human red cells of types *A*, *B* and *O* were obtained from normal persons and non-cancer patients, and from cancer patients.

Red cells from normal persons were washed three times in saline and incubated with incomplete anti-*D* serum for 1½ hr. at 37° C. Non-sensitized controls were obtained by incubating cells with serum from group *AB* persons. All cells were then re-washed three times and made up to 30 per cent suspensions in saline, and tested for sensitization by the addition of appropriate dilutions of rabbit anti-human-globulin serum.

Intact hæmoglobin-free red-cell membranes were prepared by the gradual hæmolysis method previously described[2], mounted on carbon-filmed grids, shadowed with chromium and examined with an RCA *EMU–2C* electron microscope.

Almost all the non-sensitized cells from normal persons were found to have the typical structure, with plaques of diameter 200–500 Å. (mean diameters 350–400 Å.) (Fig. 1*a*). After sensitization, the plaque diameters were much larger (500–800 Å.). Of 25 sets of cells from normal persons examined before sensitization, only 2 had a mean plaque diameter greater than 500 Å. ; after sensitization, 16 of the 25 samples had plaques of diameter 500–800 Å. (Fig. 1*b*). In 58 per cent of the specimens from cancer patients, the plaques were of similar size whereas only 30 per cent of non-cancer patients showed plaques in this range. When the results were compared with those of the antiglobulin test, they indicated, in any event in the cancer group, a strong correlation between a positive test and abnormal plaque size.

It appears, therefore, that either natural or experimental modification of the red cell surface, so that cells give a positive antiglobulin test, is associated with enlargement of the surface plaques.

We have recently found that ghosts of red cells can be sensitized to give a positive antiglobulin test ;

Table 1

Cell samples from	No. of cell samples with:			Totals
	Antiglobulin test	Average plaque diameter High	Average plaque diameter Normal	
Non-cancer patients	Weak positive	7	2	9
	Negative	6	28	34
	Total	13	30	43
Cancer patients	Weak positive	25	2	27
	Negative	6	20	26
	Total	31	22	53

such cells show the same surface changes as those sensitized before hæmolysis.

The facts that changes in the surface of red cells of more than half the cancer patients tested could be detected by electron microscopy, and that the change is readily induced by sensitization with incomplete antibody, suggest that many such cases have a similar type of antibody on their red cells. This would confirm our previous results[3] showing that anti-globulin tests on the red cells of cancer patients were significantly more often positive, albeit weakly, than in non-cancer patients and very much more so than in healthy people.

HISTOCHEMISTRY

Pigment Bodies of the Spinal Neurones of Some Teleosts

PIGMENT bodies have been observed in the untreated living spinal neurones of the frog *Rana tigrina*[1] and some reptiles[2]. As I could demonstrate corresponding pigment bodies in the spinal neurones of some teleosts, these bodies must no doubt be considered to be of more general importance. The species investigated in this connexion were *Nannostomus beckfordi*, *Phenacogrammus interruptus*, *Corynopoma riisei*, *Otocinclus vestitus*, *Chriopeops goodei*, *Phalloceros caudimaculatus*, *Nanochromis nudiceps* and *Ctenopoma kingsleyi*.

The spinal neurones were studied in the living condition under the phase-contrast microscope and with basic dyes used *super vitam*. In this way the pigment bodies presented themselves as discrete, dirty-yellow to dark-brown bodies. The pigment, a refractile, pale yellow substance, appeared to be confined to certain duplex lipid bodies only. As in reptiles[2], this was not seen in any of the fixed preparations. The living neurones of the teleosts may reveal in addition a diffused pigment in the cytoplasm, like that of *Rana tigrina*[1], and the water snakes[2]. The general coloration of the ganglia in these teleosts and reptiles[2] was not pale yellow, in spite of the pigment in the neurones, unlike that in *Rana tigrina*[1]. As in reptiles[2], the pigment bodies in the teleostean neurones were distributed at random, although they tended occasionally to aggregate. In general, these bodies consisted of spheroids, sub-spheroids and particulates with irregular contours varying in diameter, approximately 1–4μ. Some of these bodies displayed variously distorted binary structures. The cells, which abounded in these pigment bodies, rarely contained lipid particulates.

The formaldehyde-calcium (gelatin and Helly-Zenker-Bouin) paraffin sections of the ganglia, stained with ethanolic sudan black *B*[3], revealed some pigment bodies fairly coloured, while other bodies in the same site were only partly positive. With chrome alum hæmatoxylin the pigment bodies give a strong positive reaction, with periodic acid–Schiff and methyl green/pyronin *G* a faint red coloration, while the reaction to sudan IV was almost negative. The plasmal reaction of these bodies appeared to be negative and the performic acid–Schiff reaction gave erratic results. The fat solvents, ether, chloroform, cold ethanol, cold and hot acetone and hot pyridine, appeared to be resisted by such bodies. The reaction to most of the dyes was negative. A few of them were found to segregate neutral red *super vitam* and coloured somewhat red. A negative result was obtained with Lison's test for carotenoids tried on gelatin sections of formaldehyde-calcium[3] fixed material. Moreover, the other tests for carotenoids (formic acid, hydrochloric acid, sulphuric acid, trichloroacetic acid and Carr–Price reaction), when applied to the living ganglia, reacted negatively with the pigment bodies. As in reptiles[2], on the strength of these results these pigment bodies must probably be considered as lipofuscins. Moreover, accumulations of brownish-black pigment bodies, defying all the histochemical reactions mentioned here, were observed in the surroundings of the entire ganglion.

According to Sharma[2] and correctly in my opinion, these pigment bodies are not the secretory products from the classical Golgi apparatus as claimed by Moussa and Banhawy[4], since one has not found any such apparatus or even a remotely comparable structure either in the living or in the processed young neurones. Identical views are held by Thomas[5], Baker[3], Nath[6] and Malhotra[7]. On the other hand, the pigment bodies appear to have originated as a result of total or partial oxidation of some of the lipid bodies. Cohn[8] also advocated the participation of lipids in the synthesis of pigment. The significance of this oxidation resulting in the pigment accumulation is unknown.

The pale yellow, refractile pigment, which was demonstrated in the cores of certain duplex lipid bodies (*vide supra*) originated in all probability within the interna of the lipid particulates or Golgi bodies of Hirsch in much the same way as described by Baker[3], Lacy, Hirsch and Kanwar[9]. In the neurones of *Iphita limbata* (Hemiptera) a neurosecretory product occurs, which Nayar[10] considers as lipofuscins. At this stage it is unknown whether or not the pigment bodies of reptiles[2] and teleosts could be correlated with the neuro-secretory product of *Iphita limbata*[10]. In any event it is certain that these products bear a close histochemical relationship, inasmuch as both contain lipofuscins.

Nucleolar Localization of Succinic Dehydrogenase in Normal Rat Hepatic Cells

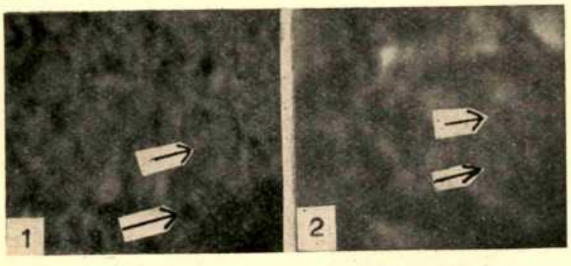
SCRUTINY of the literature[1–6] revealed that the oxidative enzyme, succinic dehydrogenase, is present in the mitochondria, occasionally in the cell membranes[2], of all mammalian cells. The absence of this enzyme in the nuclei including the nucleoli is a very characteristic feature, except in bird erythrocytes, which according to Brachet[7] may be due to the fact that bird erythrocytes have no mitochondria.

This report describes the cytochemical localization of succinic dehydrogenase in the nucleoli of normal rat hepatic cells besides their well-established cytoplasmic counterpart.

Frozen sections (8μ) of rat liver were cut, removing the endogenous substrates for succinic dehydrogenase in ice-cold 0·1 *M* phosphate buffer. Then the sections were incubated for 1 hr. at 37° C. in a medium containing 5 c.c. 0·1 *M* phosphate buffer *p*H 7·6, 5 c.c. 0·1 *M* sodium succinate, 5 c.c. distilled water and 10 mgm. triphenyl tetrazolium chloride. The common controls for confirming specificity of the reactions were applied[4,5,8]. The tetrazolium salt used in this experiment is considered to be very suitable for its high tissue penetrating power and the monochromatic nature of its formazan[9].

In the formazan-stained section, the same hepatic cell was studied with and without a phase-plate under a Zeiss phase-contrast microscope. During each of the two observations, photomicrographs were taken. Then the formazan colour was extracted from the above section by post-fixing it in Carnoy acetic alcohol and restained with pyronin methyl green for staining the nucleoli[10]. From the vernier readings of the mechanical stage recorded previously, pyronin methyl green-stained cells, in the same microscopic field as that of the formazan cells stained with formazan, were studied. A photomicrograph was taken.

It was observed that cytoplasmic formazan granules of rat-liver cells were stained in the usual manner; they showed the topography of mitochondria. The nuclei remained completely unstained and clear without any diffusion of cytoplasmic formazan inside them. In regard to shape, size and position, nucleolar-like formazan deposits of the same formazan-stained cell, with and without a phase-plate, yielded the same results as nucleoli extracted with formazan and stained by pyronin methyl green. The photomicrographs present evidence for nucleolar succinic dehydrogenase, and this unusual finding, besides the well-established cytoplasmic aspects of mitochondrial activity, is quite new.



Figs. 1 and 2. Arrows point to the nucleolar-like formazan deposits of the same formazan-stained hepatic cells without and with phase-contrast, respectively. (× 1,170)

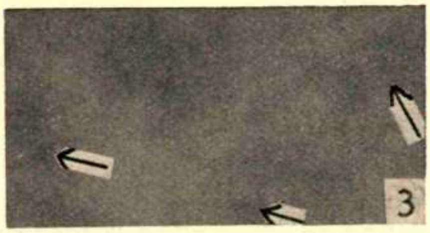


Fig. 3. Arrows point to the formazan-extracted and pyronin methyl green-stained nucleoli of hepatic cells of the same microscopic field (without phase-contrast). (× 1,340)

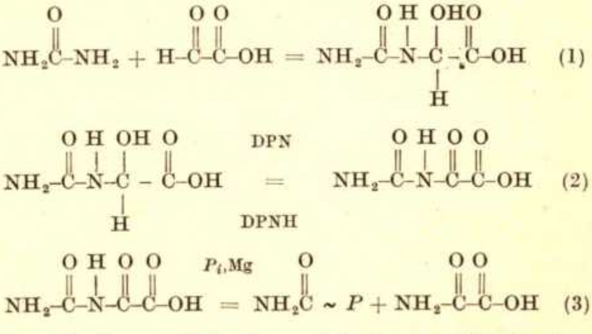
MICROBIOLOGY

Phosphate-dependent Degradation of Urea

Jones and Lipmann[1] recently proposed a direct mechanism for the phosphorolysis of urea. We have found that urea is phosphorolytically cleaved by extracts of *Streptococcus allantoicus*. However, the urea moiety is indirectly decomposed as made evident by the requirement for glyoxylate. Co-factors for the following scheme of urea degradation in which glyoxylurea is an intermediate are diphosphopyridine nucleotide (DPN), magnesium, and phosphate or arsenate:



$$\mathrm{NH_2\overset{O}{\overset{\|}{C}}{-}NH_2 + H{-}\overset{O}{\overset{\|}{C}}{-}\overset{O}{\overset{\|}{C}}{-}OH = NH_2{-}\overset{O}{\overset{\|}{C}}{-}\overset{H}{\overset{|}{N}}{-}\underset{H}{\underset{|}{\overset{OH}{\overset{|}{C}}}}{-}\overset{O}{\overset{\|}{C}}{-}OH} \quad (1)$$

$$\mathrm{NH_2{-}\overset{O}{\overset{\|}{C}}{-}\overset{H}{\overset{|}{N}}{-}\underset{H}{\underset{|}{\overset{OH}{\overset{|}{C}}}}-\overset{O}{\overset{\|}{C}}{-}OH \overset{DPN}{\underset{DPNH}{=}} NH_2{-}\overset{O}{\overset{\|}{C}}{-}\overset{H}{\overset{|}{N}}{-}\overset{O}{\overset{\|}{C}}{-}\overset{O}{\overset{\|}{C}}{-}OH} \quad (2)$$

$$\mathrm{NH_2{-}\overset{O}{\overset{\|}{C}}{-}\overset{H}{\overset{|}{N}}{-}\overset{O}{\overset{\|}{C}}{-}\overset{O}{\overset{\|}{C}}{-}OH \overset{\mathit{P_i},Mg}{=} NH_2\overset{O}{\overset{\|}{C}} \sim \mathit{P} + NH_2{-}\overset{O}{\overset{\|}{C}}{-}\overset{O}{\overset{\|}{C}}{-}OH} \quad (3)$$

Oxamic transcarbamylase catalysing reaction (3) has been previously described by Valentine and Wolfe[2].

Procedures used for growth of *S. allantoicus* and preparation of cell-free extracts have been described previously[2,3]. Degradation of urea was measured under the following conditions: a suitable amount of an enzyme fraction[2] was incubated with 100 μmoles

Table 1. CO-FACTORS OF UREA DEGRADATION

Tube No.	Constituent omitted	Oxamate formed (μmoles)
1	Glyoxylate	0·0
2	Enzyme*	1·5
3	Urea	0·0
4	Arsenate	1·7
5	DPN	0·0
6	$MgSO_4$	4·9
7	None	14·1

* A dialysed enzyme fraction precipitated by ammonium sulphate (ref. 2) was used, 1·1 mgm. of protein being added per tube.

sodium glyoxylate (Sigma), 100 µmoles urea, 40 µmoles potassium arsenate (*p*H 7·5), 1 µmole DPN, 5 µmoles magnesium chloride, and water to a final volume of 1 ml. Reaction-time was 1 hr. at 30°. Oxamic acid, formed in the series of reactions mentioned above, was measured in the manner of acetamide in the hydroxamate method of Lipmann and Tuttle[4]. 'Dowex' chromatography of oxamic acid was carried out using 'Dowex 1–*X*8' (formate). Glyoxylic acid and glyoxylurea were estimated by the method of Young and Conway[5]; protein was determined by the method of Lowry *et al.*[6]; urea was determined according to the method of Archibald[7].

Co-factor requirements for urea degradation are shown in Table 1. The extract used in these experiments also contains enzymes which cleave glyoxylate. Products of this pathway (to be reported elsewhere) react in the assay of Lipmann and Tuttle[4] but contain no nitrogen and can be distinguished from oxamate. In the experiment described in Table 1 this blank amounted to 4 µmoles per tube and has been subtracted. 100 µmoles of methylurea, ethylurea, and thiourea, respectively, were tested as substitutes for urea but were found to be inactive, being below or near the blank value for the omission of urea. The role of arsenate and phosphate in oxamate formation from urea and glyoxylate is shown in Fig. 1. 2 µmoles of potassium arsenate catalysed the formation of 14 µmoles of oxamate in this reaction. Higher concentrations of inorganic phosphate (P_i) gave similar results. Carbamyl phosphate formed in this reaction was measured by coupling with the ornithine transcarbamylase system as reported previously[3]. Fig. 2 is an elution diagram obtained by 'Dowex' chromatography of the compound formed enzymically in the standard reaction mixture. The elution peak of the enzymically synthesized compound corresponds to that of potassium oxamate.

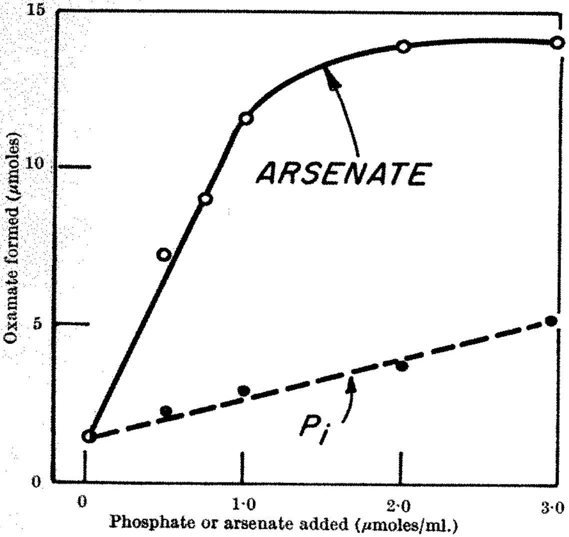


Fig. 1. Arsenate or phosphate requirement for oxamate formation from urea and glyoxylate. Standard reaction mixture

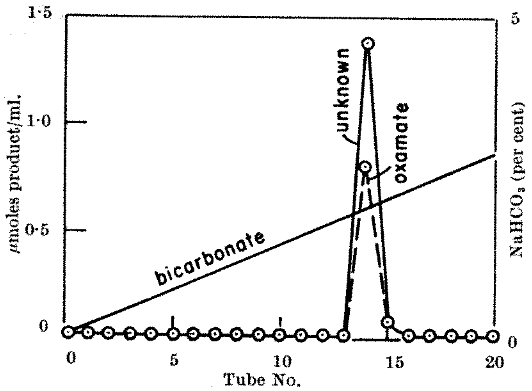

Fig. 2. 'Dowex 1-*X*8' (formate) elution diagram of potassium oxamate and the product formed enzymically from urea and glyoxylate

Energy derived from the urea moieties of allantoin is utilized by *Streptococcus allantoicus* for growth. It was of interest to see if this organism could obtain energy directly from urea. No direct phosphorolytic cleavage of urea was observed; rather, urea combined with an aldehyde moiety and was degraded indirectly via glyoxylurea and carbamyl oxamic acid to carbamyl phosphate and oxamic acid.

This investigation was sponsored by the National Science Foundation grant 6453.

Use of Cellulose Acetate Membranes for detecting Penicillinase-producing Organisms

DURING investigations into the gain or loss of penicillinase in cultures of staphylococci[1] there was a need for a simple method of screening these so as to be able to detect small numbers of penicillinase positive or negative organisms in mixed cultures. In addition, in the study of hospital cross-infection a quick reliable method was required for investigating many different strains of staphylococci for penicillinase production. A number of chemical and microbiological methods for detecting the ability of organisms to destroy penicillin have been described[2-7]. However, none of the methods in common use is really adapted for the study of mixed penicillinase-positive and negative populations on the surface of solid media, nor is it easy to use them so as to detect a few colonies of one type in the presence of a predominant growth of the other. One of the most useful diagnostic methods for pour plates is that described by Manson, Pollock and Tridgell[8]. We have modified their method by pouring agar containing penicillin and Andrade's indicator gently over colonies growing on the surface of agar plates, but under these conditions the method is not so sensitive nor so reliable as when deep cultures are used.

The method described here is suitable for use with surface cultures ; it can be used entirely as a chemical method or can be combined with microbiological confirmation showing that microbiologically active penicillin has disappeared. Essential features of the technique are as follows : Cultures were inoculated on to the surface of an 8-cm. cellulose acetate membrane (Oxo, Ltd.) previously laid on a nutrient agar plate. The inoculum was usually 0·1 ml. of a suitably diluted culture which was spread on the membrane with a glass spreader so as to give 100–200 colonies per membrane. Inoculation could also be made by means of Lederberg's velvet pad technique[9] from master plates containing suitably spaced colonies. In the examination of many strains of bacteria, as required in the investigation of air flora, each strain was inoculated on to one square of the grid marking of membranes which are supplied already marked. Inoculated membranes were then incubated overnight, though when the inoculum was replicated on to the membrane incubation for a few hours was adequate. After incubation the membrane was removed with forceps and placed gently on to three Whatman No. 1 filter papers which were previously moistened with 3–4 ml. of a solution of penicillin *G* containing 25,000 units per ml. with Andrade's indicator (2·0 per cent) contained in a Petri dish. After quite short periods of incubation, often as little as a few minutes, penicillinase-producing colonies developed a pink colour which slowly spread into the filter paper but did not stain the surrounding membrane to a great extent. Usually 2-hr. incubation was used in order to detect weak penicillinase producers.

Penicillinase production could also be induced by exposing cultures to low concentrations of a powerful inducer such as methicillin ('Celbenin')[10]. This could be done either by placing the membrane with its colonies on pads soaked in a solution of methicillin (0·5 μgm. per ml.) and incubating for about 2 hr. or by placing the membrane on a nutrient agar plate containing 0·1–0·5 μgm./ml. of methicillin and then inoculating it and incubating overnight before transferring it to the pad containing strong penicillin *G* solution.

The method could be combined with a microbiological method by the following variation. The membrane, instead of being placed on the surface of a nutrient agar plate, was placed on the surface of a plate containing 0·01–0·05 μgm./ml. of penicillin *G* in nutrient agar and then inoculated. After incubation the membranes were removed and tested for penicillinase as described above. The area on the plates previously occupied by the membranes could now be inoculated by means of a velvet pad loaded with a confluent growth of *Sarcina lutea* known to be highly sensitive to penicillin. If penicillin had been destroyed during the growth of the test organisms on the membrane, then the *Sarcina lutea* grew on the area below the colonies.

If a mixed culture was diluted sufficiently to give single colonies, it was possible to detect which colonies had destroyed penicillin. This, taken together with the production of penicilloic acid as indicated by the pink colour given by Andrade's indicator, made it easy to confirm in an experiment whether a group of colonies in a culture were capable of destroying penicillin and if so whether they did it by means of penicillinase or by some other mechanism.

BIOLOGY

A Hypodermic Probe using Fibre Optics

It has long been the desire of physicians, physiologists, and biophysicists alike to be able to observe, microscopically, living human tissue in its original environment. Numerous ingenious approaches to the problem have been made, and there are few organs of the experimental animal that have not been subjected to transillumination and microscopic examination in the living state, either *in situ* or externally. However, in spite of marked advances in these various techniques, none has proved suitable for the microscopic examination of human tissue *in vivo* at any depth.

If an ideal system is to be developed for this application, its resolving power should approach the average wave-length of visible light in order to permit observation of the many structures, such as striations of the muscle, which are only a little greater than one micron in size. It is also important that such a system should transmit all visible wave-lengths without selective absorption, thus permitting the use of the standard vital staining techniques at present used to improve the contrast between tissues of otherwise similar optical properties. In addition, the system should permit magnification adequate to utilize fully the advantages of such high resolution and colour reproduction.

Recent advances in the field of fibre optics[1,2] have made feasible the development of such a system, incorporated in a hypodermic probe. Theoretical and experimental work on the properties of glass fibres of very small diameter[3] has shown that it is possible to use fibre bundles, containing cores as small as 1μ in diameter, to transmit images in colour over considerable lengths. Such a fibre bundle, 0·5 mm. in diameter, would contain approximately 200,000 fibres, each capable independently of conveying light along its length, and would, under magnification, give a resolution element of about 1μ.

A distinct advantage to be gained from the use of a fibre optical, as compared to a conventional optical, system in such an application is that it obviates the necessity of introducing a lens system into the tissue under observation. In this instance it is far more satisfactory to place the entrance end of the fibre bundle in contact with the object under examination and illuminate the object either by 'trans-illumination' or 'vertical illumination' using an externally placed light source.

Fig. 1*a* illustrates diagrammatically a probe for the examination of human muscle tissue *in situ*, using a vertical illumination system. Two other methods of illumination are diagrammatically illustrated in Figs. 1*b* and 1*c*. Fig. 2 shows the prototype instrument constructed for preliminary experimentation. This instrument consists of a fused fibre bundle of 0·064 in. diameter and 1·5 in. long comprised of cores of 0·001 in. diameter contained within a standard 15-gauge hypodermic needle. To protect the fibre bundle against breakage during insertion, it is normally retracted into the hypodermic needle. In order to observe the muscle tissue, the bundle is extended beyond the needle, once inserted, and brought into contact with the tissue. This movement within the needle is controlled by a trigger. The light source and condensing system are located at right angles to the optical axis of the system, and the fibre bundle is illuminated by a perforated reflector. The image cast on the end of the fibre bundle is viewed through the perforation by a low-power microscopic system.

Fig. 3 shows a photograph taken through the instrument while in use to observe blood vessels in frog mesentery using a trans-illumination system. When vertical illumination was used with this instrument the image contrast was found to be low due to back-scattering and reflexion.

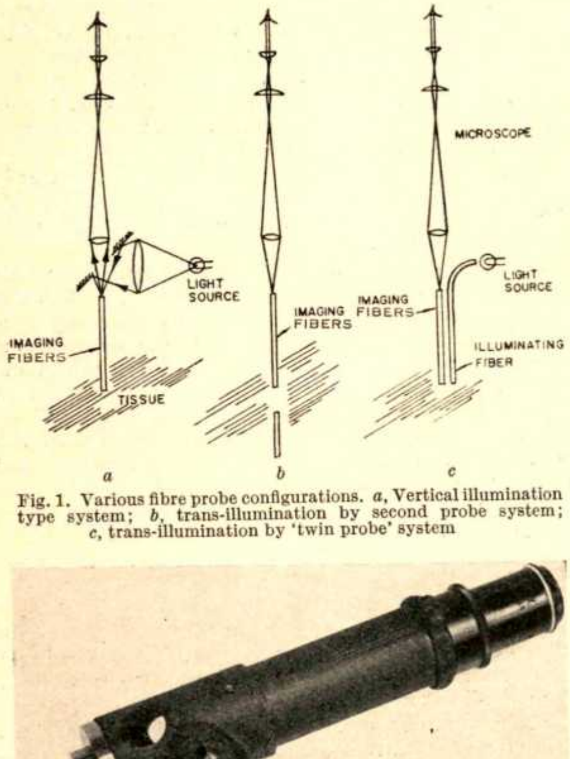

Fig. 1. Various fibre probe configurations. *a*, Vertical illumination type system; *b*, trans-illumination by second probe system; *c*, trans-illumination by 'twin probe' system

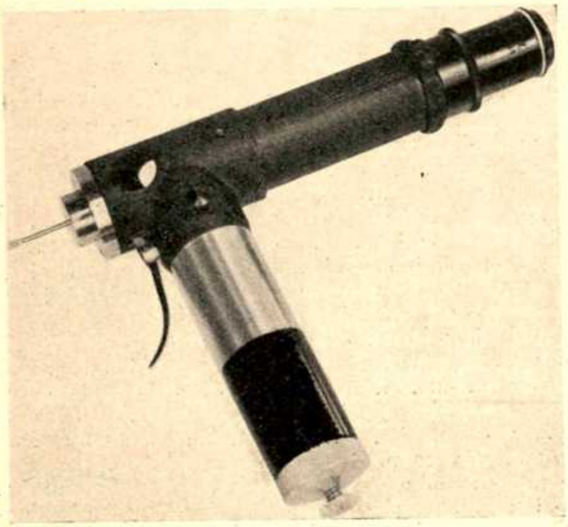

Fig. 2. Protot ype hypodermic fibre optics probe

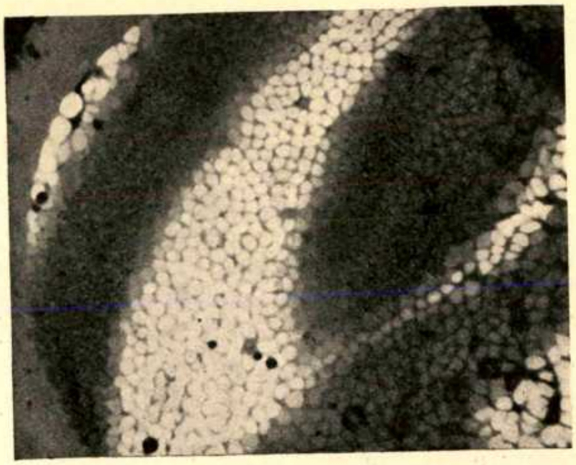

Fig. 3. A view of the arteries in the mesentery of a living frog taken by trans-illumination

It is interesting to note that, although the average size of an individual blood corpuscle in the circulatory system of the frog is the same order of magnitude as the fibre diameter, the motion past the end of the fibre probe was clearly visible due to refractive index changes varying the illumination condition of the fibres.

The results of preliminary experiments with this prototype instrument indicate numerous potential applications. Further work along these lines would allow a complete review of morphological relationships to be undertaken in the living human being under normal and pathological conditions. It would be possible, for example, to conduct biopsies on suspect nodules without incision or excision. Similarly, living bone marrow studies and liver biopsies could be performed easily. The optical system of the probe could be utilized as a carrier for micro-electrodes or micropipettes, allowing measurement of electrical activity of living cells under direct observation, for example in the brain or muscles, and permitting the injection of drugs or vital stains. Clinically, the optical probe could be used by the neurosurgeon to determine his position in the brain from the local architectonics under visualization in preparation for obliterative chemosurgery, the obliterative chemicals being injected through the same probe. Such an optical system would be compatible with near ultra-violet light transmission and could be used for the investigation of natural or induced fluorescent phenomena in the body.

Further work is in progress to produce fibre optics probes capable of 1μ resolution. These probes will be designed to operate under conditions of vertical illumination or transillumination and with visible, near ultra-violet, and polarized light.

Seasonal Fluctuations and Distribution of Nitrite in a Tropical West African Estuary

VERY little is known about the distribution and seasonal fluctuations of inorganic nitrogen in West African estuaries. I have given[1] some preliminary figures based on a series of spot analyses and found that in the Sierra Leone River estuary there are both horizontal and vertical gradients in the concentrations of nitrite, nitrate and ammonia, with the higher values in the upstream direction and with increasing depth. The concentration of nitrite was found to vary from 8 to 4 mgm. nitrogen/m.^{3}, nitrate from 141 to 74 mgm. nitrogen/m.^{3} and ammonia from 22 to 10 mgm. nitrogen/m.^{3}—samples taken over a period of only 3 months were, however, examined.

The present investigation was carried out in the Sierra Leone River estuary over a period of one year, using the Griess–Ilosva method for determining nitrite nitrogen as modified by Orr[2] and Wattenberg[3]. Only the nitrite content of the estuarine water was determined in this investigation, but it is hoped that later it will be possible to study the seasonal changes and distribution of both nitrate and ammonia in order to throw some light on the nitrogen cycle. It is probable that fluctuations in nitrogen and phosphorus may, with other factors such as the amount of effective light, be responsible for the phytoplankton 'bloom' which has been shown by Bainbridge[4] to occur during the period January–July. This 'bloom' was also found by me[5] and by Bainbridge[6] to coincide with an increase in the fat content of the local shad, *Ethmalosa dorsalis* (C. & V.), which is caught in the estuary in fairly large numbers.

Fig. 1 shows the average concentration of nitrite in the surface water for the central region of the estuary during the year 1960. There is a marked seasonal fluctuation, with the higher values occurring in the wet season (June–November). The maximum concentration of nitrite and minimum salinity do not, however, fall within the same month; this suggests that nitrite accumulates in the drainage area during the dry season (October–May) and is removed at the beginning of the wet season. The increment to the nitrite content of the estuary through the direct action of rainfall was not measured; but it may be appreciable since large quantities of dust of Sahara origin are removed from the atmosphere by the convectional rains in June and early July.

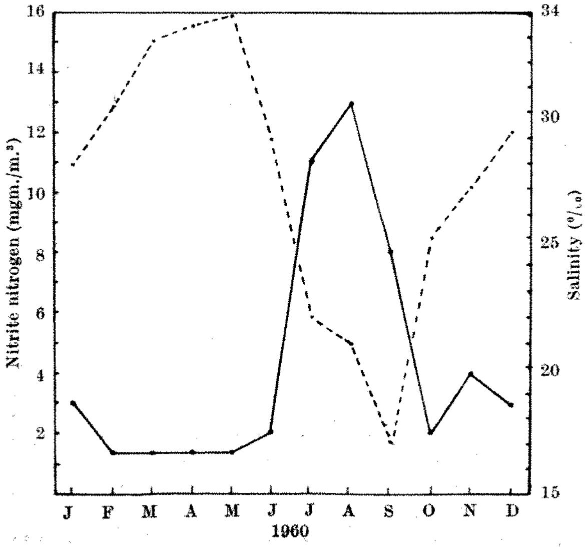

Fig. 1. Seasonal fluctuation of nitrite in the surface water for the central region of the Sierra Leone River Estuary. Nitrite, ——; salinity, - - - -

Nitrite values for the feeder streams are also high in the wet season—a fact which suggests that the high values for nitrite in the estuarine water are not entirely due to increased turbulence as a result of the larger volume of fresh-water entering the upper reaches at this time of the year. I[7], and also Longhurst[8], have shown that the bottom deposits in the central region of the estuary are largely composed of muds with a relatively high organic content, whereas in the upper reaches and mouth the deposits consist of sand or gravel. From this distribution of the organic material in the estuary, it would be expected that vertical mixing should result in higher nitrite values in the central reaches rather than at the two ends, since the suspended material in the central reaches would contain a higher proportion of organic matter brought up from the bottom. That this is actually the case may be seen from Table 1, although the amount of nitrite contributed by the suspended detritus is clearly less than that from the feeder streams.

Table 1. CONCENTRATION OF NITRITE IN THE ESTUARY WATER

Range of salinity (gm. per 1,000 gm.)	Average nitrite nitrogen (mgm./m.^{3})	No. of observations
0–15	8	15
16–20	10	13
21–25	10	26
26–30	4	73
> 30	1	27

Values for nitrite obtained during the flood and ebb at springs and neaps differed by no more than 1 mgm. nitrogen/m.^{3} during the dry season and 3 mgm. nitrogen/m.^{3} during the wet season. The horizontal gradient was most marked in the wet season; in July, the average value for nitrite at the mouth was 7 mgm. nitrogen/m.^{3} and 18 miles upstream 13 mgm. nitrogen/m.^{3}. During the greater part of the dry season, however, nitrite appears to be fairly evenly distributed in the surface water throughout the length of the estuary.

Diurnal Rhythm in Cave Crayfish

NUMEROUS investigations have suggested persistent diurnal physiological rhythmicity to be the rule among organisms, inhabiting the natural day–night environment. However, the only report known to me of results of a study of an animal fully removed for innumerable generations from such daily changes in light and temperature, the case of the cave crayfish, *Orconectes pellucidus* (Tellkampf), clearly established that these possess no difference in activity between day-time and night-time when kept under controlled conditions in the laboratory[1].

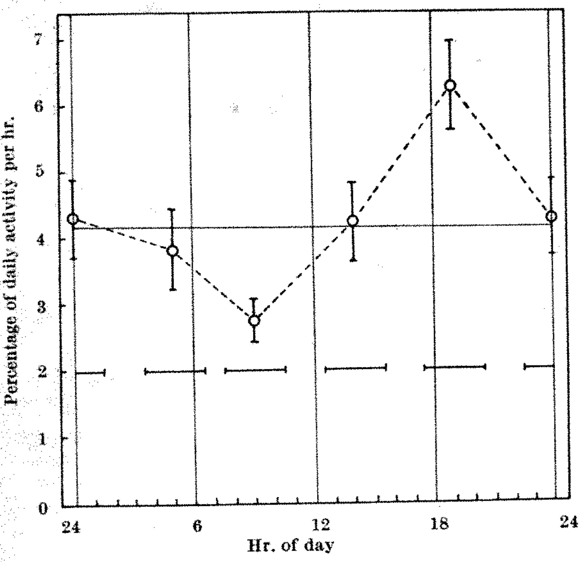

Fig. 1. Relation between the percentage of daily activity and hour of day for 3-hr. periods shown by the horizontal bars. Standard errors of means are indicated

However, a re-examination of the published data[1], in the light of recent advances in our knowledge of persistent diurnal rhythmicity in metabolism, has indicated a statistically significant ($P < 0\cdot001$), 24-hr. rhythm of activity to be present (Fig. 1) with minimum activity about 9 a.m. and maximum about 7 p.m. Activity from 8 to 10 a.m. was less than half that from 6 to 8 p.m. This relationship was found on reconsideration of all the published data for complete days in the report already mentioned for animals kept in constant darkness. There was also a statistically significant daily rhythm in standard deviation of hourly activity values.

The crayfishes involved were collected from River Styx, Mammoth Cave, Kentucky, in March 1935 and November 1936. The cave is presumed to have been formed beginning in the late Pliocene or early Pleistocene, in other words, 1–4 million years ago. The crayfishes are highly adapted to cavernicolous life. They are pigmentless and have no eyes. Young are carried on the pleopods, reportedly chiefly during winters, thus implying an annual reproductive rhythm, despite essentially no annual temperature change. Prof. Orlando Park informs me that his temperature measurements of River Styx at various times of the year during the past 25 years have varied within the range 14 ± 1° C. with no suggestion of an annual cycle.

The specific form and phase relations (times of maximum and minimum) of the diurnal fluctuation discovered resemble remarkably that of oxidative metabolism in the incubating chick egg[2], are essentially the mirror image *in toto* of the diurnal metabolic rhythm of the fiddler crab and, treating a.m. and p.m. periods independently, are related directly or as a mirror-image to the daily cycle of potato plants[3] and numerous other organisms investigated so far. These metabolic rhythms have been established to be extrinsic in character, and phase-locked to the Earth's rotation, through demonstration of day-by-day modifications, correlated with aperiodic, weather-associated fluctuations in subtle geophysical factors[4] in what had formerly been deemed conditions constant for the organisms.

This discovery of such a diurnal rhythm, especially with its particular characteristics, in an ancient cavernicolous species long shielded from any diurnal light and temperature changes gives strong additional support to the concept of the universal presence of an extrinsic 24-hr. rhythmicity timed by the Earth's rotation, available for use in turn, as the timer for specific, adaptive diurnal patterns of surface-dwelling species, phased by light or temperature cycles, or adaptively dissociated from specific, overt physiological patterns in cavernicolous species such as the cave crayfish[1].

It seems probable that the reported annual reproductive cycle reflects an extrinsic annual metabolic rhythm such as has been reported even in unvarying light and temperature[5].

Furunculosis in Lough Neagh Pollan *Coregonus pollan*, Thompson

Reports were received during the early part of August 1960 that considerable numbers of Lough Neagh pollan were dying. An inspection revealed that the north-eastern shore in the Antrim Bay area was littered with fish (approximately one for each yard of beach) and from their condition it was evident that the mortality had been occurring for some time, possibly 2–3 weeks. It has since been learned that dying and dead fish continued to be noted until the end of August at least. Although pollen was the only species noted at the time of the inspection, commercial fishermen on the lake have since stated that small numbers of bream, *Abramis bramae* L., and lake trout, *Salmo trutta* L., were also affected.

Three pollan were collected and examined macroscopically in the laboratory. Except for an apparent slight hæmorrhage at the base of the anal fin and in the surrounding area in one of the fish, nothing abnormal was noted. Despite the absence of pathological indications of bacterial invasion, cultures were prepared from the pulped kidney of each of the three pollan and these all developed colonies typical of *Bacillus salmonicida* (Emmerich and Weibel). The organism was a small, non-motile, Gram-negative staining diplobacillus fermenting glucose and mannite without gas production. There was no reaction with lactose, dulcite or saccharose; gelatine was liquefied, indole was not produced and on serum agar a profuse growth with brown pigment was produced.

The results of the confirmatory tests carried out on each of the cultures from the three pollan using gold-fish, *Carassius auratus* L., are given in Table 1. In each case the inoculum was 0·05 ml. of a saline suspension of a two-day agar slope culture, the opacity of which was approximately that of Brown No. 2 or a dilution thereof. The fish were used in groups of three.

In addition, oral infection of the gold-fish was attempted, but in none of the three cases was an infection produced.

Table 1

Dilution of inoculum	Intraperitoneal injection			Applied to scarified tissue		
	Survival (in days)	Pathological effect	*B. salmonicida* isolated	Survival (in days)	Pathological effect	*B. salmonicida* isolated
Pollan No. 1 Undiluted	1–2	General œdema and liquefaction of internal organs	+	3	Necrosis of musculature in scarified area	+
Pollan No. 2 Undiluted 1/2·5 1/5·0	3 3 3	Liquefaction of internal organs	+ + +	4 5 4	Necrosis of musculature in scarified area. Liquefaction of internal organs	+ + +
Pollan No. 3 Undiluted 1/10 1/100	2 alive alive	Liquefaction of internal organs	+	3 alive alive	Necrosis of musculature in scarified area. Liquefaction of internal organs	+

Thirty-six control gold-fish were kept during the period of the investigation and, of these, three were injected intraperitoneally with sterile saline; three others were scarified and sterile saline placed on the wounds and a further three fish were injected intraperitoneally with a culture of *B. salmonicida* which had been standardized to Brown's opacity Tube No. 2 and the suspension killed by moist heat. All the control fish together with these three groups survived.

There is therefore no doubt but that *B. salmonicida* was the epizootic responsible for the mortality of the fish in Lough Neagh, but unfortunately it is not possible to advance any plausible theories as to the reason for the outbreak. It should be noted, however, that in the Ministry's records is a report that *B. salmonicida* was responsible for the death of numbers of salmon, *Salmo salar* L., in the River Bann during the mid 1930's (Furunculosis Committee Reports: Interim, 1930; Second Interim, 1933; Final, 1935; H.M.S.O., Edinburgh).

An Example of Mechanical Co-ordination of Cilia

The membranelles (compound cilia) of the protozoan *Stentor* are arranged in a single row around the oral end of the animal. Each membranelle swings through an angle of beat of about 140° in a plane at right angles to the row, while the metachronal waves pass along the row from one end to the other. It has been established[1,2] that these membranelles are normally co-ordinated to beat in a metachronal rhythm by an internal transmission mechanism, so that the conduction of metachronal 'impulses' and the beating of the cilia are separable activities of the system, having quite different properties.

Recent observations on the cilia of lamellibranch gills[3,4] have shown that the metachronal co-ordination rate (wave velocity) can be markedly increased by an increase in the viscosity of the medium around the cilia. This would not be expected on the basis of an internal conduction theory. In work on the metachronal co-ordination of *Stentor* membranelles in media of increased viscosity, I[1,5] found that the wave velocity did not change at viscosities below about 3·5 centipoises, but that at higher viscosities the metachronal rhythm was abnormal. Further experiments on *Stentor* membranelles reported here have provided an explanation of these apparently conflicting reports.

The experimental methods used, including those of measuring the frequency of beat and the wave velocity, were the same as those described previously[1], except that in these experiments methyl cellulose was replaced by polyacrylamide as the viscous agent as recommended by Gosselin[3].

The results of these experiments are summarized in Fig. 1. The records of change of wave velocity below

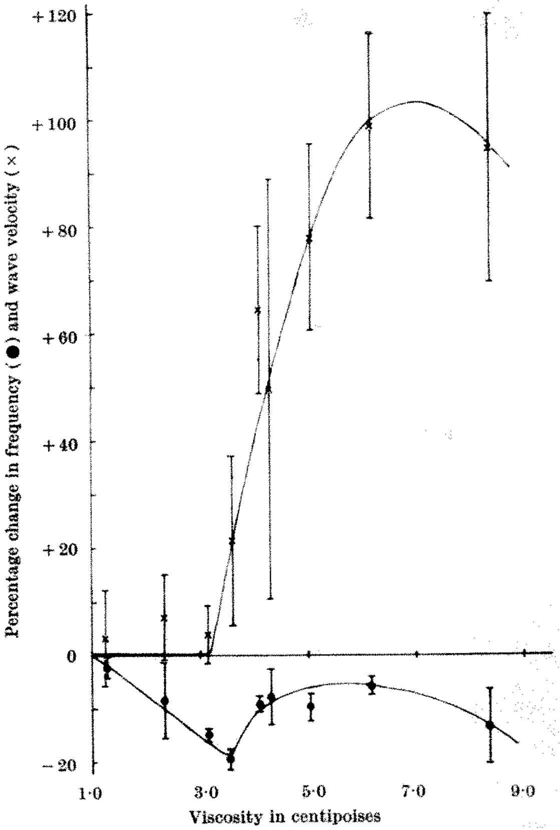

Fig. 1. Effect of polyacrylamide solutions of viscosities between 1·2 and 8·5 centipoises on frequency of beat and velocity of metachronal wave transmission of the membranelles of *Stentor*. Each value plotted is the mean of many observations, the vertical line showing 95 per cent confidence limits

3·3 centipoises were found by the *t* test ($P = 0{\cdot}05$) not to differ significantly from zero, which is in accord with previous results. At the higher viscosities there is a dramatic and significant increase in wave velocity. All the frequency records except the first differ significantly from zero, showing that at viscosities below about 3·5 centipoises the frequency steadily decreases, but it rises again at about the same viscosity as the increase in wave velocity. In solutions of high viscosity there is also an obvious decrease in the amplitude of beat.

The best explanation of these observations seems to be as follows. At the higher viscosities the tendency for the viscous medium to slow the ciliary beat falls away slightly, evidently because the movement of one cilium assists the movement of its neighbours through the increased drag communicated through the viscous medium. This same viscous-mechanical interaction between adjacent cilia allows an alternative means of communicating a metachronal rhythm which is faster than the internal co-ordination and increases in speed as the viscosity is increased. Under these conditions of high external viscosity the cilia are thought to be co-ordinated solely by the sort of mechanical means suggested by Gray[6]. The same group of cilia may thus show this second method of co-ordination under these special conditions.

The amplitude of beat decreases progressively with increase in viscosity, until eventually the angle of beat is so small that viscous interaction becomes negligible, so that the frequency falls rapidly away and the metachronal rhythm breaks down. The cilia may beat singly and sporadically at very high viscosities (above 10 centipoises) but the movements are very feeble.

A Method of replicating Dry or Moist Surfaces for Examination by Light Microscopy

THE use of transparent replicas is a convenient method for the microscopic study of surfaces. Perfectly dry structures can be replicated with plastic substances such as 'Collodion', 'Formvar' or methacrylate, but a serious disadvantage to the general use of these materials is that they 'mist' when allowed to harden in a moist atmosphere. Accordingly, they cannot be used satisfactorily with specimens that either become distorted when dry or, like many biological specimens, have a naturally wet surface. The following method, which overcomes this difficulty, consists essentially of taking a primary impression of the surface with a silicone rubber plastic and using this to form secondary transparent replicas.

Silicone rubber monomer ('Silflo Dental Plastic', Flexico Developments, Ltd., 25 Devonshire Place, London, W.1) is mixed with the requisite amount of catalyst and immediately poured over the material to be examined. The plastic hardens in about 5 min. and it is then gently lifted away with forceps. The primary replica is now washed in water containing detergent ('Teepol') with the aid of a small sable-hair brush and finally swilled in distilled water.

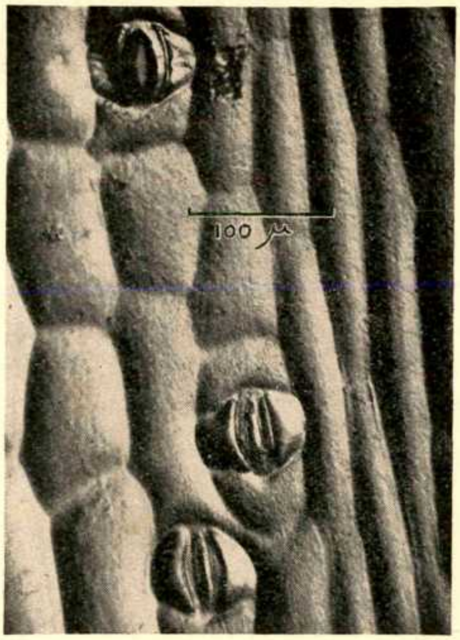

Fig. 1. Replica of abaxial surface of leaf of *Tradescantia virginiana* showing flaccid and turgid guard cells

Before proceeding to the next stage it is most important that the primary replica be thoroughly dried. The method adopted is to blot the rubber with fluff-free filter paper (Whatman No. 50) and to place it flat, impressed surface upwards, in a desiccator containing phosphorus pentoxide for 10–15 min.

A nitrocellulose preparation ('clear' nail varnish) is poured or spread over the dry, undisturbed rubber

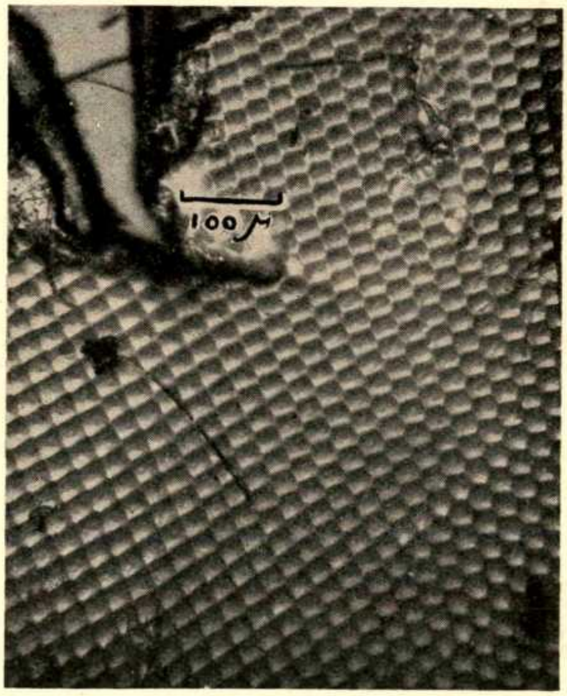

Fig. 2. Replica of surface of a wasp's eye

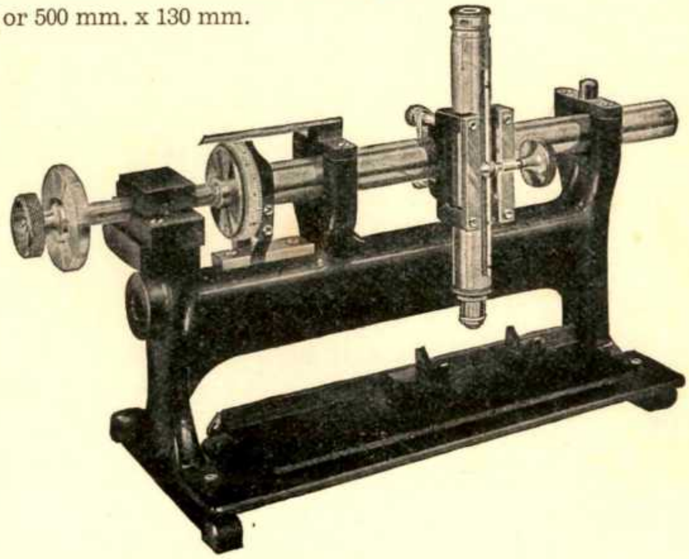
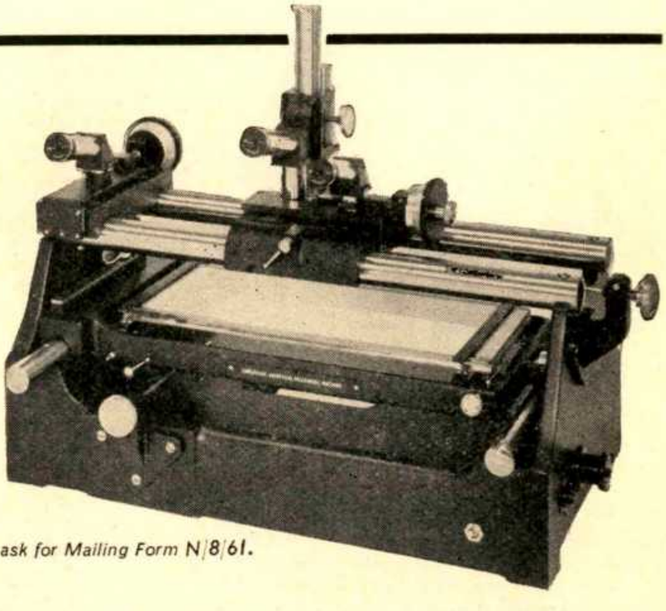
Accurate measurements
ON FLAT MATERIALS

Cambridge measuring machines and microscopes are geometrically designed and this makes possible a *lasting* degree of accuracy not easily achieved otherwise. Two basic types are made: the *Cambridge Measuring Microscope* for linear measurements up to 50 mm. and the *Cambridge Universal Measuring Machine* for two linear measurements (at right angles) either to 330 mm. x 130 mm. or 500 mm. x 130 mm.



CAMBRIDGE MEASURING MICROSCOPE

This reads directly to 0.01 mm. or by estimation to 0.001 mm. Its robust construction and easy manipulation ensure that the instrument is a useful tool both for workshop and laboratory purposes. It can be supplied with tripod and cathetometer telescope for vertical measurements.



CAMBRIDGE UNIVERSAL MEASURING MACHINE

The object is mounted on or between glass plates which have a transverse movement of 130 mm., and measurement is made by viewing through a microscope with longitudinal travel of 350 mm. (or 500 mm. in the larger model). Microscopes with micrometer adjustments read in both directions (at right angles) to 0.01 mm. or by estimation to 0.002 mm.

A convenient holder for strip film is available as an accessory.

PUROX*

RECRYSTALLISED ALUMINA 99·7%
STABILISED ZIRCONIA 97%
PURE MAGNESIA 98%

* *Registered Trade Mark*

Purox is the name of a new range of high purity Alumina, Magnesia and Zirconia refractories. These refractories contain no glassy bond, and the Alumina is impervious. They are hard, strong, and have extremely high softening points. New techniques developed at Neston allow of the manufacture of complex shapes to close tolerances, and of single parts of considerable size. These materials open up entirely new possibilities in many fields.

surface and the lid of the desiccator replaced immediately. When quite hard (10–15 min.) the transparent secondary replica may be separated and mounted between two thin, polished microscope slides, the edges of which are afterwards bound together with adhesive tape.

The stripping process may present some difficulty owing to the tendency of the replica to curl. The transparent layer should be lifted slowly and, as soon as it is free, transferred swiftly to a slide and sandwiched flat. When the mount is viewed by eye the back, that is, the unreplicated surface, should be clear. Unsatisfactory replicas look cloudy and the fault almost invariably lies in the failure to dry the primary replica.

On microscopic examination the replicas are seen to their best advantage if the sub-stage mirror is tilted to one side so that the incident light strikes the specimen obliquely.

This method is a simple, quick and reliable way of obtaining permanent records of a variety of surfaces suitable for examination by light microscopy (Figs. 1 and 2). It can be used for living tissues and, since the rubber appears to be non-toxic, serial impressions from the same region can be made provided care is taken not to damage the surface when removing the rubber.

I am indebted to Dr. F. A. L. Clowes for his encouragement and advice and to Mr. F. Bradley for the photographs.

ENTOMOLOGY

Distribution of *Acarapis woodi* (Rennie)

A. R. Brimblecombe and C. Roff state in *Nature* of May 6, p. 561, that "Mites determined as *Acarapis woodi* (Rennie) were found recently on one of the escorts with a queen bee (*Apis mellifera* L.) from California". They also report that subsequent surveys indicated that this particular mite was found on bees from other States of the United States, and was widespread in Queensland.

The queen shipment in question was sent to Brisbane in June of 1959, and the identification was made a short time later. In subsequent letters with the British Museum and with Canberra, it was determined that no evidence of the internal mite was found in the tracheæ of the bee, but only forms on the outside of the thorax. The California State Department of Agriculture and the University of California made extensive surveys of bees in California, and other apicultural workers made surveys in other States and in different Provinces of Canada, examining thousands of bees for the internal mite, *Acarapis woodi*, with entirely negative results. No specimens of *A. woodi* have ever been found in the United States or Canada.

External acarapis mites were found widely scattered in both the United States and in Canada, and these were identified as *Acarapis dorsalis* and *A. externus*. These mites are innocuous forms that apparently have a world-wide distribution and cause no noticeable damage. They have never been found to invade the tracheæ of bees and can be distinguished from *Acarapis woodi*, the internal species, by several distinct morphological as well as ecological characteristics, which are now known to the acaralogists of the British Museum (Natural History) and to the National Museum in Washington. I personally have sent slides of the external mites to both museums and to various places in Australia, including Canberra and Adelaide.

If there is any doubt still in the minds of the acaralogists as to whether the external acarapis mites are distinct species or merely 'strains' of one mite, then for scientific as well as economic reasons they should identify the external forms as *A. woodi dorsalis*, or *A. woodi externus*, or *A. woodi vagans*, whichever they chance to be. It is certainly not by chance that the external acarapis mites have distinctly different physical characters from the internal mite, or that they have never been found to invade the tracheæ of their host.

Brain Hormone of the Silkworm, *Bombyx mori*

It is generally accepted that the neurosecretory cells concerning the metamorphosis of insects contain a small amount of a secretory substance at any time of development[1,2], notwithstanding a marked effect which they exert when implanted or transplanted. This means that accumulation of the secretory substance released continuously from the cells in the brain is necessary to become effective. This is the reason why a great many brains were used to extract a sufficient amount of the active principle[3]. However, we have found that only several devitalized brains of *Bombyx mori* could cause adult differentiation when inserted into the non-diapausing pupæ of *Philosamia cynthia ricini* caused to diapause by prompt removal of their brains just after pupation. Devitalization was brought about by various ways such as subjecting brains to freezing in a deep-freezer at $-18°$ C. for 21 days, desiccating them over silica gel for one day, or heating them at 90° C. for 90 min. After being treated, the brains were all proved to be as effective as live ones, so far as they were tested by five for each test pupa. Needless to say that in this case the brain hormone, enough to stimulate adult differentiation of the recipient, had to be present in the five inserted brains. The possibility that the adult differentiation was caused by the prothoracic gland hormone which contaminated the inserted brains can be ruled out, since neither the same amount of fatty tissue nor blood similarly treated exerted any perceptible effect on the dormant pupæ. It seems, however, worthy of mentioning that after treatment brains of *Philosamia* were inferior to brains of *Bombyx* in their effectiveness. This presumably indicates that the situation at a given moment is different between the two species, a larger amount of the hormone being contained in the latter.

Kobayashi and Kirimura[3] reported first the preparation of the brain hormone. In their case, however, an extract from some 400 brains was necessary to let each pupa develop into an adult. By contrast, our finding stated above may suggest that the extraction from only five brains would yield sufficient quantity of the active principle, if the procedures of extraction are successfully manœuvred.

Thus we started work on the chemical properties of the brain hormone after Kobayashi and

Kirimura's method with the view of getting an active principle from the small number of brains.

The complexes of brains and subœsophageal ganglia from pupæ of *Bombyx* that had been mostly shortly before the completion of adult development were stored in a deep-freezer at – 18° C. and used as material to be extracted. Brains were counted before crushing to facilitate an easy computation of dose per test pupa. All the work was carried out at room temperature.

240 brains (fresh wt. 97 mgm.) were homogenized with 1 ml. of methanol and centrifuged. The same extraction was repeated twice more with the residue. The extracts thus obtained were combined and dried *in vacuo*. A small amount of yellow matter thus prepared was dissolved in 2 ml. of distilled water plus 5 ml. of ether, the latter being removed after thorough shaking. The water layer was washed with ether twice more and a trace of ether remaining in the water was removed *in vacuo*. The water fraction thus obtained was made up with distilled water to 2 ml., 0·1 ml. of which was injected into each of 20 test pupæ of *Philosamia*. 19 out of the 20 pupæ metamorphosed into moths 18–24 (average 19) days later at 25° C. (At this temperature normal pupæ can emerge as moths 17–19 days after pupation.) The combined ether washings were dried also *in vacuo* to yield yellow oily matter. It was dissolved in 2 ml. of sesame oil and 0·1 ml. of the solution was injected into each of 20 test pupæ with the result that not one of them indicated an appreciable differentiation toward adult. Control experiment of injecting water or sesame oil alone proved also to be ineffective. A repetition of the same experiment yielded essentially the same result.

The active principle was also prepared by extraction with 2 per cent sodium chloride solution. 350 brains were homogenized with 0·7 ml. of the saline solution and centrifuged at 9,000 r.p.m. for 30 min. The same procedure was repeated three times more with the residue, and the extracts thus obtained were about 2·8 ml. All 37 pupæ, in which 18 pupæ were injected each with 0·1 ml. of the extract and 19 with 0·05 ml., were able to metamorphose into moths 18–25 (average 20) days and 19–25 (average 21) days later respectively. Injection of 0·1 ml. and 0·05 ml. of the saline solution brought about no sign of adult differentiation.

Thus it is evident that the active extract of the brain hormone can be prepared successfully from a relatively small number of brains. Here it must be emphasized that there is an important difference between our finding and that obtained by Kobayashi and Kirimura: namely, our principle is water-soluble, while that obtained by Kobayashi and Kirimura is ether-soluble, as tested by the water–ether partition. Further purification now in progress will give further information about the chemical nature of the brain hormone.

We are indebted to Dr. S. Morohoshi, director of Gunze Silkworm and Mulberry Research Institute, and Dr. S. Sasaki, director of Ayabe Branch of Sericultural Experimental Station, who supplied the silkworm pupæ.

GENETICS

Sterile Crosses between Mutations of *Tribolium confusum* Duv.

'McGill Red' is a wild strain of *T. confusum* maintained by me for some thirty years. 'McGill Black' is a jet black mutation which arose in the wild strain in 1950. The life-histories of both strains have been described by H. M. Slatis and me[1]. In the spring of 1960 another black mutation which may be called for convenience 'Slough Black' was received from the Pest Infestation Laboratory at Slough. An extensive programme of research has been under way to study the genetics of 'Slough Black' in relation to 'McGill Black' and 'McGill Red'.

It has been found that, when females of 'McGill Black' are mated to any male other than that of 'McGill Black', numerous eggs are produced, but these are all non-viable, no development occurring. The males of all the genotypes obtainable from crosses between the three strains have been mated with females of 'McGill Black' with similar results.

The eggs have been sectioned, but there is no trace of development, and eventually the eggs dry up and wither. Superficially they appear quite normal. There would seem to be four possible causes: (*a*) the matings are ineffective, no sperms being transferred; (*b*) there is some genetic lethal effect; (*c*) there is a cytoplasmic defect; (*d*) there is the faint possibility that rearing the insects on flour plus yeast has had an effect. Further work is being done on this problem, and some stocks are being reared on flour plus wheat-germ to check (*d*).

5-Methyltryptophan and Darkening of the Hair in Yellow A^y/a Mice

Previous experiments have shown that powdered preparations of the skin and hair of yellow (A^y/a) mice oxidize L- (but not D-) tryptophan and also DL-5-hydroxytryptophan with the production of yellow solutions[1,2]. To obtain further evidence on the question of whether tryptophan, or a derivative, might be implicated in the production of yellow pigment in the hairs of this strain of mice, *in vivo* experiments were carried out using an antimetabolite of tryptophan[3]. Starting at 3–4 days of age, daily subcutaneous injections of DL-5-methyltryptophan were made in these mice for a period of 7–10 days. This is a period of vigorous pigment production. (Mice were obtained from the R. B. Jackson Memorial Laboratories, Bar Harbor, Maine. DL-5-methyltryptophan was a product of Sigma Chemical Co., St. Louis, Mo.)

While lower doses gave equivocal results, the injection of 1 mgm./gm. DL-5-methyltryptophan into these suckling mice daily for a week (a dosage high enough to cause measurable depression in growth-rate) resulted in animals the coats of which were markedly less yellow than those of animals given saline or L-tryptophan daily (Table 1). Instead, coats of experimental animals appeared darker in colour than those of controls. When unstained 10μ cross-

Y, Yellow pigment; *B*, black pigment; *Y* + *B*, yellow and black pigments both visible in the hair cross-section studied. A rectangular piece of dorsal skin and hair was fixed in formalin, embedded, cut at 10μ, and examined without any staining. At least five cross-sections of skin were examined in each case. Counts were made of a series of 100 or more consecutive cross-sections of hairs. To avoid duplication, hairs were counted at a given level parallel to the surface of the skin. Colour was estimated under the microscope with daylight illumination, and with the source of the slide unknown. This table gives no information on the relative distribution of pigments at other points along a given hair.

sections of skin and hair were examined; those from experimental animals could be readily distinguished because of increased amounts of black pigment in the follicles and hairshafts. Quantitatively, the percentage of hairs containing visible black pigment increased from 1–10 per cent in controls to 40–70 per cent in the experimental animals (Table 2). The effect depended on the continued injection of the methyltryptophan; two animals were kept after the completion of one experiment without further injections, and a typical yellow coat was visible under the dark outer coat of hair after about a week.

Preliminary trials failed to demonstrate a reversal of the darkening effect by the simultaneous administration of an equal amount of L-tryptophan daily; however, since in mice injected tryptophan is rapidly metabolized by an inducible enzyme system in the liver[4], it may take a very large amount of systemically administered tryptophan to antagonize the effect.

The above results support the idea[1] that tryptophan, or a derivative, may be utilized for pigment formation by these mice. If the methyltryptophan acts primarily by inhibiting this system, the increase in black pigment may be a secondary effect. It is well known that neural crest cells, or dendritic melanocytes of *Ay/a* mice, form black pigment rather than yellow in locations other than the hair bulb: the ear skin, the harderian gland, and the nictitans, for example[5], as well as when transplanted into the follicles of genetically black mice[6], or when explanted into the chick cœlom[7]. That the appearance of the black pigment may be a secondary effect is supported by some equivalent experiments on the effect of methyltryptophan on black (*C57Bl*/6) mice. Here, injections of the analogue resulted in a slight diminution in the intensity of black pigmentation. This result, while not quantitative, shows that methyltryptophan does not in itself have a stimulating effect on the system responsible for forming black pigment, namely, the tyrosinase system. The only other explanation would have to be that the methyltryptophan competes successfully with both the yellow and black systems to form an 'intermediate' black, which seems unlikely.

The experiments reported here are in agreement with the idea that yellow pigment in the hairs of *Ay/a* mice represents not simply a different degree of polymerization of melanin formed by the tyrosinase system, but is formed, at least in part, by a different route.

I am indebted to Dr. L. B. Flexner, of the Department of Anatomy, University of Pennsylvania, Philadelphia, and to Dr. R. K. Enders, of the Zoology Department, Swarthmore College, Swarthmore, Pa., for facilities for the initiation and completion of this work. Part of the work was carried out during tenure of a U.S. Public Health Service postdoctoral fellowship.

Genetics of a Difference in the Male Genitalia of East and West African Stocks of *Papilio dardanus* (Lep.)

THE famous African butterfly *Papilio dardanus* Brown is highly polymorphic in the female, while the males are monomorphic and non-mimetic[1]. The species has been divided taxonomically into a number of sub-species, mainly on the basis of quantitative variation in wing pattern of the males[2–4]. Several of these races are isolated from all others on islands and mountainous areas. However, five named races are not geographically isolated from their neighbours and the male wing pattern, since it tends to show a clinal distribution, is unsatisfactory for delimiting their exact distributions. The western race (*dardanus*) might be thought to be more distinct than the others, because of the morphology of the male genitalia[4]. In the eastern races there is a long spine on the inner surface of the valve; the western race usually has no spine (Fig. 1). In a narrow zone north of Lake Victoria where the races meet, both types are found, together with intermediates with very short spines, which in west Africa are known only as rarities.

During recent investigations into the genetics of *P. dardanus*[5], we have accumulated information on the mode of inheritance of the long spine of eastern races. The histograms (Fig. 2) show the distribution of spine-length in the western males from the region of Lake Victoria, the eastern males from South Africa, the F_1 and F_2 hybrids between the stocks,

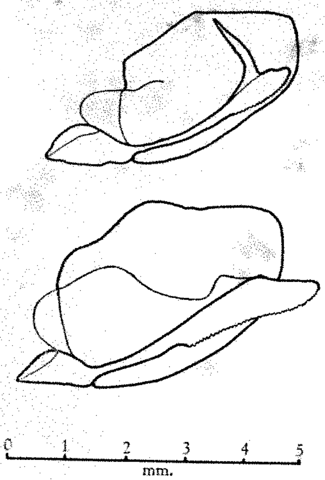

Fig. 1. The upper drawing shows a valve of the male genitalia of the eastern type; the lower one that of a male of the western race. In the latter, note the absence of the long spine present in the eastern males

and the back-cross broods to west African material. The results demonstrate that the presence of the spine is dominant to its absence, and that the character is controlled in the main by a single major gene. If we divide the F_2 individuals into two groups at the antimode (at 2·5 units) we find a ratio of 107 long-spined to 30 short- or no-spined individuals. This is a satisfactory approximation to the expected 3: 1 ratio ($P > 0·3$). The back-cross broods containing 25 long-spined to 20 short- or no-spined individuals also give a satisfactory approach to the expected 1: 1 ratio ($P > 0·3$). Variation between broods in the mean length of the spine of the dominants, coupled with the less clear-cut division into two classes in the F_2 compared with the parental populations and back-cross broods, suggest that modifiers are segregating in the hybrids.

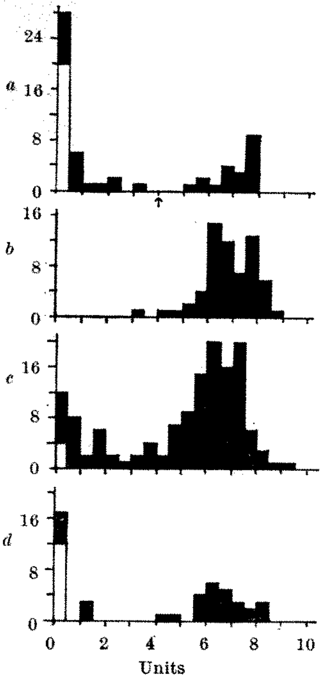

Fig. 2. The histograms show the numbers of males with different spine lengths in various stocks of *P. dardanus*, each unit being 0·156 mm. (*a*) To the left of the arrow at 4 units, all the males are of the western race, to the right of the arrow, of the eastern race; (*b*) the F_1 hybrids between the eastern and western races; (*c*) the F_2 hybrids; (*d*) the backcross of the F_1 to the western race. The white area of the histogram between 0 and 0·5 unit shows the number of individuals with no spine

The morphology of the male genitalia has been used in Lepidoptera and some other insects as an important or often the only taxonomic character. These results show that one such character, used to separate a sub-species, is mainly controlled monogenically.

The similarity between the histogram of the F_2 broods and histograms compiled for such human characters as the threshold for the ability to taste PTC solutions, or the ability to metabolize isoniazid[6], suggests that a more detailed picture of the genetics of spine-length in *P. dardanus*, where breeding can be controlled, may serve as a useful model in detailed investigations of the genetics of human characters having a bimodal distribution.

AGRICULTURE

Plant Growth in Irradiated Soil

One of the difficulties in any investigation of the action of micro-organisms on plants growing in soil is that sterilization of the soil by heat or by chemical means prior to planting causes complex physical and chemical changes, some of which are phytotoxic[1]. The reports that urease activity continued in soil sterilized by an electron beam[2] and that γ-irradiation of humus resulted in little physical and chemical change[3] indicated that irradiation sterilization may overcome the disadvantages of soil sterilized by more conventional methods. The present report is concerned with a comparison of growth of subterranean clover (*Trifolium subterraneum* L.) in two soils (Urrbrae red-brown earth and Mount Compass podzolized sand) sterilized by heat, by propylene oxide and by irradiation.

Soil was added to 20·5 cm. × 3·2 cm. test-tubes to a depth of 5 cm. and moistened to field capacity with distilled water. These were sterilized either by steam at 120° C. for 1 hr. on each of three successive days, or by propylene oxide introduced into an evacuated sterilization chamber at the rate of 0·6 gm./litre capacity and held at 25° C. for 72 hr. Other samples of the moistened soils were sealed in polythene bags placed in sealed tins and sterilized by γ-irradiation with a dose of 2·5 megarads. The bags were afterwards opened and placed in sterile test-tubes. All sterilization was carried out fourteen days before planting with surface-sterilized subterranean clover seed pre-germinated on agar[4]. Three sterile germinating seeds were transferred to each of eight tubes in each treatment and grown for six weeks in a glasshouse with supplementary heating and cooling.

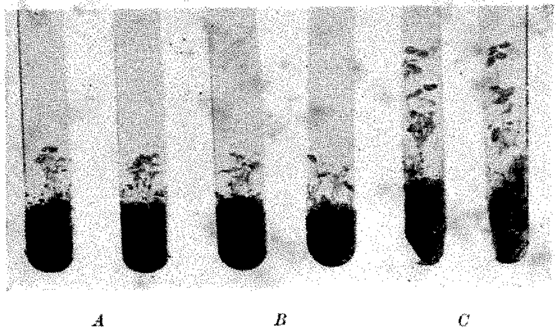

Fig. 1. Growth of subterranean clover in Urrbrae red-brown earth at 3 weeks. *A*, Heat-sterilized; *B*, propylene oxide treatment; *C*, irradiation-sterilized

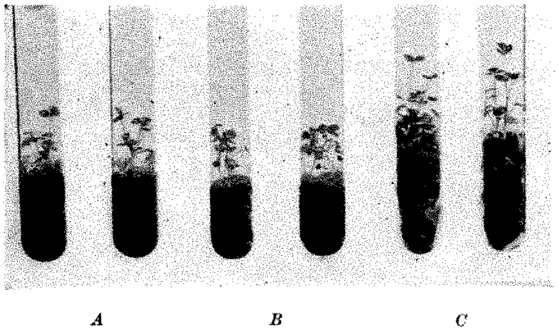

Fig. 2. Growth of subterranean clover in Mount Compass sand at 3 weeks. *A*, Heat-sterilized; *B*, propylene oxide treatment; *C*, irradiation-sterilized

Plating of soil at both planting and harvesting showed that whereas heat- and irradiation-treated soils were sterile, the soils treated with propylene oxide were not. In this treatment there were some surviving bacteria which proliferated in all tubes during the experiment.

In both Urrbrae red-brown earth and Mount Compass sand, plant growth and development in soils sterilized by heat or propylene oxide was retarded, plants in the latter case being particularly small, with rosetting and yellowing. Several of these plants died during the six-week experimental period. By contrast, plant growth in irradiated soil was good (Figs. 1 and 2, Table 1) and only slightly less than that of plants growing in unsterilized soil.

In irradiated Mount Compass sand, roots and root hairs were well developed, but in heat-sterilized sand, root growth was significantly less, light brown lesions occurring on some roots, and root hairs being few, short, and irregularly distributed. In heat-sterilized Urrbrae red-brown earth, severe stunting of primary and the many secondary roots occurred, with dark brown lesions frequently present; root hairs were absent. Subsequent experiments have shown that the phytotoxic effects produced by heat sterilization of soil can be overcome by the introduction of specific fungi and bacteria. While no obvious stunting of roots occurred in irradiated Urrbrae red-brown earth, root hairs were short and sparse compared with those on plants in unsterilized soil.

Table 1. Growth of Subterranean Clover in Heat- and Irradiation-Sterilized Soils after 6 Weeks

Soil	Mean total root length/tube		Mean total top weight/tube	
	Heat (cm.)	Irradiated (cm.)	Heat (mgm.)	Irradiated (mgm.)
Mount Compass sand	46·1	86·1**	23·4	29·0
Urrbrae red-brown earth	16·9	86·5***	33·4	40·5***

** Differences between heat- and irradiation-sterilization significant at 1 per cent level.
*** Differences between heat- and irradiation-sterilization significant at 0·1 per cent level.

The results suggest that this method may be the best at present for work on plant growth in sterilized soils. However, the suppression of root-hair formation and growth (especially in Urrbrae red-brown earth) indicates that irradiation is not without some deleterious effect. In fact, recent experiments with irradiated Urrbrae red-brown earth stored at room temperature for 10 weeks prior to planting indicate that phytotoxicity increases in such soils with storage. This result parallels the observation[5] that colour and odour changes occur in grass following irradiation sterilization, due possibly to the continued enzyme activity[2].

We wish to thank Dr. J. G. Clouston, of the Australian Atomic Energy Commission, Lucas Heights, New South Wales, for irradiation of the soils.

Assessing the Damage caused by *Heterodera rostochiensis* Woll.

Previously there have been no published accounts of the effect of any species of *Heterodera* on the yield of the host crop under field conditions. Jones[1] attempted to obtain conditions approaching those found in the field by the use of small, artificially constructed plots or microplots. However, these were too small to give a realistic estimate of yield per acre. For insect pests differential population density-levels have been established by the use of insecticides. This is impractical, for eelworms as nematicides, in addition to affecting the eelworm population, also often exert an effect on plant growth. I have therefore investigated the effect on the yield of potatoes of differences in initial density of eelworm population. This method, possibly with some modification, should prove suitable for other *Heterodera* species or for any species of nematode for which reliable population estimates can be made.

Six experiments all on various fen peat soils were performed in 1960 on fields chosen for uniformity of soil depth, texture and previous cropping. Twenty small plots (each 4 rows × 5 yd.) per site were distributed on a grid pattern covering a total area of 44 rows × 80 yd. These were marked out and soil sampled (25 cores per plot) shortly after planting and the eelworm population on each plot was estimated by the usual technique[2]. The crop yield was obtained by hand digging the whole of each plot and riddling over a $1\frac{1}{2}$ in. riddle.

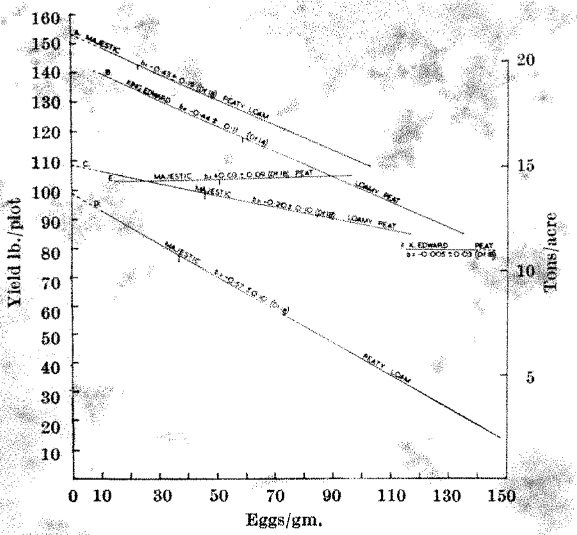

Fig. 1. The regressions of yield on eggs/gm. (The *F*-line should continue to 456 eggs/gm.)

Regression analyses were computed of yield on 'full' cysts per 100 gm. (square root transformation) and also on eggs per gm. (log transformation). A full cyst is defined as one containing more than 50 eggs.

Table 1. REGRESSION COEFFICIENTS

Site	$\sqrt{\text{Full cysts/100 gm.}}$	Log eggs/gm.
A	− 9·08 ± 2·74†	− 26·40 ± 6·70‡
B	− 10·34 ± 2·15‡	− 49·40 ± 11·20‡
C	− 5·21 ± 1·81†	− 14·37 ± 6·69*
D	− 12·25 ± 1·64‡	− 33·30 ± 5·40‡
E	+ 2·16 ± 2·05	+ 5·27 ± 9·30
F	− 0·91 ± 1·80	− 4·64 ± 17·49

* Significant at P = 0·05.
† Significant at P = 0·01.
‡ Significant at P = 0·001.

Significant regressions were obtained at sites *A–D*. At sites *E* and *F*, on adjoining farms and extremely acid peat soils, yield appeared to be independent of eelworm population and no explanation can be advanced at the moment.

The eelworm population estimates were transformed because the error increases with the size of the count. For ease of interpretation and because it seemed that yield and initial eelworm population were linearly related over the range studied, regression coefficients for sites *A–D* were also calculated from untransformed data. The regressions of yield on eggs per gm. are shown in Fig. 1 and the results for full cysts and eggs summarized in Table 2. The range of full cyst counts was approximately 0–55 per 100 gm. for each of the sites *A–D*.

Table 2

Site	Full cysts/100 gm.		Eggs/gm.	
	Regression coefficients	Yield loss/ 10 full cysts/ 100 gm. (tons/acre)	Regression coefficients	Yield loss/ 20 eggs/gm. (tons/acre)
A	−0·93 ± 0·44	1·29	−0·43 ± 0·19	1·20
B	−1·10 ± 0·24	1·53	−0·44 ± 0·11	1·22
C	−0·64 ± 0·25	0·89	−0·20 ± 0·10	0·56
D	−1·59 ± 0·26	2·21	−0·57 ± 0·10	1·58
	Means	1·48		1·14

The mean figures for yield reduction on these four sites are about 1½ tons per acre for every 10 full cysts per 100 gm. and a little more than 1 ton per acre for every 20 eggs/gm. Although efforts were made to pick uniform sites, estimates of loss of yield due to eelworm will be to some extent biased, if there are unknown soil factors which vary within these fields and have an effect on yield and on eelworm population. These preliminary trials need to be repeated in different seasons on the same and on different soils.

In advisory work it has been necessary to decide on a 'critical value' for eelworm population above which advice has been given that a satisfactory yield of potatoes is unlikely. For example, Johnson and Thompson[3] gave a figure for Yorkshire of 50 cysts with contents per 100 gm. However, damage is a continuous process commencing at low levels of eelworm and approaching a maximum when visible symptoms appear in the crop. (It is uncertain what happens at very low levels at which there might be no effect or even a slight stimulation to growth[4-6].) On all sites except *D*, where some patchiness occurred, no obvious symptoms of eelworm attack were seen throughout the growing season. Also, what constitutes an acceptable potato yield will depend on how much the crop has cost to grow, and on the cropping potential of the field, and the 'critical value' will therefore vary accordingly. This is portrayed in Fig. 1 where the lines although nearly parallel are widely separated. It therefore seems more logical to express losses due to eelworm in terms of x tons per acre for every y eelworms per z gm. of soil before planting.

I wish to thank F. G. W. Jones and B. M. Church, of Rothamsted Experimental Station, for their helpful advice on the presentation of these results.

SOIL SCIENCE

Role of Interparticle Forces in Development of Upper Plastic Limit of Clays

THE standard laboratory test method in soil mechanics for determination of the liquid limit of clays (upper plastic limit) depends on the facility of movement of particles relative to one another under conditions created by the test procedure. An interpretation of the upper plastic limit of clays has recently been suggested[1] in terms of distance between particles or structural units of particles wherein forces of interaction become sufficiently weak to allow slipping to occur.

Since the standard liquid limit test requires the samples to be remoulded in the performance of the test itself, initial structure or orientation of particles in the undisturbed or natural state is not of prime importance. The degree of particle interaction arising from interparticle forces of attraction and repulsion will determine to a large extent the facility for movement of particles. The distance between particles or structural units of particles following the remoulding of soil sample for test may be better characterized in terms of degree of particle interaction arising from influence of interparticle forces. In many natural soils, where the presence of interparticle forces may not be felt except within very close limits, particle interaction dependent on effective specific surface area may be the criterion for establishment of the liquid limit. In tests on selected clay soils using distilled water and ethylene glycol ($C_2H_4(OH)_2$), the influence of interparticle forces and effective specific surface area on the moisture content at the liquid limit is demonstrated. Correction for the specific gravity of ethylene glycol was made in the calculation of moisture content expressed in terms of the ratio of weight of fluid to the oven-dry weight of solids. The clay soils selected for test were natural bentonite, kaolinite, fire clay (primarily illite) and ball clay (approximately 75 per cent kaolinite with remainder illite, montmorillonite, feldspar and quartz). Table 1 summarizes the results of the tests.

Table 1. LIQUID LIMIT OF SELECTED CLAY SOILS WITH DISTILLED WATER AND ETHYLENE GLYCOL

Soil type	Moisture content at liquid limit (per cent)	
	Distilled water	Ethylene glycol
Natural bentonite	437·0	114·6
Kaolin	70·2	97·4
Ball clay	62·6	105·3
Fire clay	39·0	42·7

As would be predicted, the liquid limit of bentonite is reduced considerably when ethylene glycol is used in place of water. This is in accordance with the concept of interaction volume, and with results presented by previous investigators on the influence of electrolyte concentration on liquid limit[2,3]. The elimination or reduction of interparticle forces of repulsion reduces the interaction volume and thereby decreases the liquid limit.

The results for kaolin and ball clay show an increase in the liquid limit with the use of ethylene glycol in place of water. This would suggest that the resultant structure or orientation of the particles is of a dispersed nature. Although remoulding in water would tend to cause the soil to have a dispersed structure, the slightly acidic nature of the soil and the edge charges associated with kaolinite would cause the particles to reassume an edge-to-face particle arrangement. The resultant interaction volume, in a situation where edge-to-surface particle orientation exists, is small compared with that of a dispersed structure. For purposes of consideration in terms of a mechanism, it may be expedient to visualize slipping of particles or flocs of particles at the critical liquid limit point being dependent upon the external surface area. In this instance, in the absence of interparticle forces of any significant magnitude, the dominant factor is the external specific surface area which would require a sufficient coating of fluid only for lubrication purposes. Particle interaction would be in terms of facility of movement of particles relative to one another.

The absence of strong interparticle forces in the fire clay accounts for the very slight increase in liquid limit in the substitution of glycol for water. The initial structure of the clay soil mixed with water is dispersed, and subsequent replacement of water by glycol yields the same structure or orientation of particles.

Complete data and test results on other properties of the soils described will be published elsewhere.

Soil Temperatures in Iceland

INFORMATION on soil temperatures in Iceland is scant except for interrupted and now discontinued observations made by the Meteorological Bureau of Iceland at two and earlier three different locations in the country[1]. These observations had mostly been restricted to the 1- and 2-m. depths.

A study of the influence of soil temperature on the soil–plant relationships has therefore been undertaken, especially with the more effective use of fertilizers in mind.

Preliminary measurements at three agriculturally important depths, namely, 5, 10 and 20 cm. under permanent grass and in an exposed soil, were carried out at the experimental ground of this Institute during the summer 1960. The soil at the particular site was a coarse sandy loam with 10–15 per cent loss on ignition.

All measurements were carried out with permanently installed mercury-in-glass soil thermometers with a collar of non-hardening roof-compound around the soil-air joints to exclude so far as possible free air temperature gradients caused by the shrinking of soil around the inserted parts of the thermometers. Readings had to be restricted to the normal working hours of each day and were made at 9 a.m. and 5 p.m., local summer time (= G.M.T.), thus usually giving six morning observations and five in the afternoon of each week.

Table 1 shows a few typical weekly mean values of the soil temperatures thus obtained.

The highest soil temperatures noted under the grass cover during the above period occurred in mid-July as follows: at 9 a.m., 13·6, 14·0 and 14·0° C.,

Table 1. TYPICAL WEEKLY MEAN VALUES OF RECORDED SOIL TEMPERATURES AT 5, 10 AND 20 CM. DEPTHS UNDER PERMANENT GRASS AND IN AN EXPOSED SOIL AT VARMA, ICELAND

Week	Under grass						Exposed soil					
	9 a.m.			5 p.m.			9 a.m.			5 p.m.		
	5 cm.	10 cm.	20 cm.	5 cm.	10 cm.	20 cm.	5 cm.	10 cm.	20 cm.	5 cm.	10 cm.	20 cm.
1/6– 4/6	9·5	9·8	9·5	10·9	10·1	9·4	9·8	9·0	9·1	13·1	11·9	9·2
7/6–11/6	11·2	11·6	11·2	13·4	12·0	11·3	10·4	10·2	10·6	14·8	13·5	10·9
11/7–16/7	13·1	13·6	14·0	15·8	14·4	14·0	12·6	12·5	13·1	20·9	17·1	14·1
8/8–13/8	12·2	12·8	13·3	13·9	13·5	13·4	11·9	11·7	12·9	19·9	16·9	13·7
5/9–10/9	10·5	11·0	11·5	11·0	11·2	11·4	9·0	9·6	10·6	11·7	11·1	10·7
26/9– 1/10	8·3	8·6	8·8	9·2	9·0	8·8	7·3	7·8	8·1	9·7	9·1	8·7

respectively at the 5, 10 and 20 cm. depths, while corresponding values at 5 p.m. were 16·8, 14·8 and 14·1° C., respectively. In the bare soil the highest temperatures observed at 9 a.m. were 14·2, 14·0 and 15·0° C. at the above depths, while corresponding values at 5 p.m. were 22·6, 19·0 and 15·5° C., respectively. It should be mentioned that the highest temperatures noted at each soil depth do not necessarily coincide, but may occur at different dates.

The highest air temperatures observed at these two hours of observations were 15·8 and 19·2° C., respectively.

Ground frost as recorded 5 cm. above ground occurred only twice over the bare soil, but 8 times above the grass during the period of observations. The lowest grass-minimum temperatures recorded were in June −1·1° C., in July −0·2° C., in August −1·3° C. and in September −2·2° C.

This limited material does not allow for much discussion, but it gives some valuable indications for future work on the processes of soil formation in Iceland. It also provides additional paths for studies of ecological differences in the country's natural vegetation, but fuller information is needed before definite conclusions can be reached. Therefore further work is in progress.

PSYCHOLOGY

Perceptual Defence and Filter Theory

It has been suggested by Broadbent[1] that his general theory of selective processes in the human nervous system could give an account of the phenomenon of perceptual defence. His theory assumes that information entering the central nervous system can be thought of as arriving along certain 'channels' and that a 'filter' can select one (or occasionally more) channels and suppress the input along others. He has said: "It is economical for a series of stimuli to be analysed first for simple physical properties conveying little information . . . (if) classes of words may behave in the same way as sensory channels do . . . the filter might detect that a word belongs to the general class of sexual words without distinguishing which of those words it is and pass the word to the later perceptual mechanisms for more detailed analysis if the filter is set to pass sexual words. . . . The main factual point at which evidence seems to be needed is the question whether a class of words can act in the same way as a sensory channel".

On this last point one may comment that a class of words, where class is defined by meaning only, has no physical characteristics common to all its members. Hence if the filter works on physical characteristics, as stated above, it would not be able to select such a class without selecting the individual members in it, which Broadbent was trying to avoid.

To accept his suggestion leads to the following prediction. The threshold for detecting what class a word belongs to should be lower than that for identifying individual members of that class. The present communication presents an experiment to test this.

Two lists of monosyllabic words were prepared on magnetic tape, seven words in each list. These were played to subjects at different signal-to-noise ratios. Two groups of undergraduates were used as subjects. Group A ($n = 14$) were presented with a list of colour names, and asked to make a forced choice at each signal-to-noise level as to whether the class of words was colours or animals. They were also given the second list and asked to identify the individual words on it, without being told anything about the context. The list was actually the names of clothes. This design biases the experiment in favour of the prediction, due to the effect of context on threshold[2]. Group B used the lists the other way round (clothes for class, and colours for individual, recognition). The results are shown in Figs. 1 and 2.

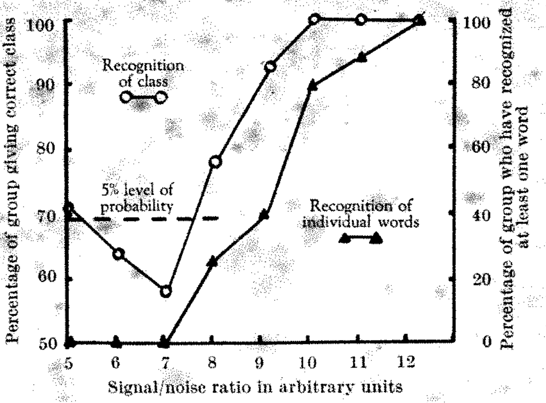

Fig. 1

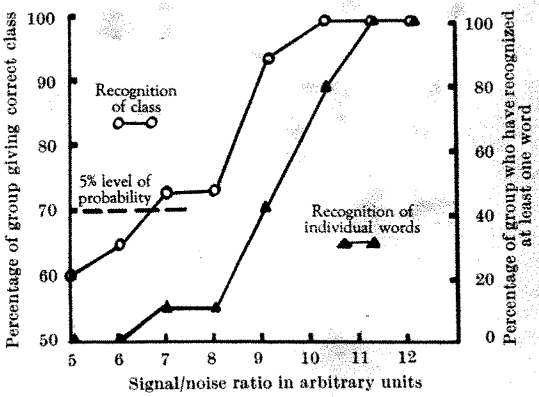

Fig. 2

For both lists the point at which the class recognition curve rises above the 5 per cent level of confidence (by the binomial test[3]) is also the point at which the first words are recognized correctly. Since contextual help was given for the class-recognition thresholds but not for the individual word-recognition thresholds, the curve for the latter is, if anything, displaced farther than it should be to the right. This finding agreed with the subjects' introspections.

Thus the prediction from Broadbent's theory is not fulfilled, and we must conclude that classes of words cannot function like a sensory channel, at least in this type of situation.

FORTHCOMING EVENTS

Wednesday, August 30—Wednesday, September 6

British Association for the Advancement of Science (at Norwich)—123rd Annual Meeting.

Wednesday, August 30

At 8 p.m.—Sir Wilfrid Le Gros Clark, F.R.S.: "The Humanity of Man" (Presidential Address).

Thursday, August 31

At 10 a.m.—Prof. D. J. E. Ingram: "From Radar to Spectroscopy—New Regions of the Spectrum" (Kelvin Lecture).

At 10 a.m.—Prof. R. G. W. Norrish, F.R.S.: "Chemistry and Spectroscopy" (Presidential Address, Section B).

At 10 a.m.—Prof. C. M. Yonge, F.R.S.: "Life and Environment on the Bed of the Sea" (Presidential Address, Section D).

At 10 a.m.—Sir Gordon Radley: "World Communications" (Presidential Address, Section G).

At 10 a.m.—Dr. H. E. Holttum: "Plant Taxonomy as a Scientific Discipline" (Presidential Address, Section K, K*).

At 10 a.m.—Sir William Slater, F.R.S.: "The Revolution in Agriculture" (Presidential Address, Section M).

At 11.15 a.m.—Dr. L. Chalk: "Wood Anatomy" (Chairman's Address, Section K*).

At 11.30 a.m.—Prof. Max Gluckman: "African Jurisprudence" (Presidential Address, Section N).

At 8 p.m.—Prof. C. D. Darlington, F.R.S.: "Why People are Different" (*Eidophor* programme).

Friday, September 1

At 10 a.m.—Dr. R. Stoneley, F.R.S.: "The Interior of the Earth" (Presidential Address, Section A).

At 10 a.m.—Prof. K. C. Dunham, F.R.S.: "Black Shale, Oil, and Sulphide Ore" (Presidential Address, Section C).

At 10 a.m.—Prof. S. H. Beaver: "Technology and Geography" (Presidential Address, Section E).

At 10 a.m.—Prof. Sir Bryan Matthews, F.R.S.: "Senses and the Sciences" (Presidential Address, Section I).

At 10 a.m.—Dr. B. E. Lawrence: "Education in Uganda" (Presidential Address, Section L).

At 11.15 a.m.—The Earl of Cranbrook: "Science and Social Service" (Presidential Address, Section X).

At 11.30 a.m.—Prof. George Seth: "From Galton to Crowther" (Presidential Address, Section J).

At 8 p.m.—Field Marshal Viscount Alanbrooke: "Some Birds of Spain" (Evening Discourse).

Saturday, September 2

At 8 p.m.—Prof. S. Tolansky, F.R.S.: "Seeing the Very Small" (*Eidophor* programme).

Sunday, September 3

At 11 a.m.—Service in Norwich Cathedral. Preacher: The Lord Bishop of Norwich, the Right Reverend Dr. Launcelot Fleming.

Monday, September 4

At 10 a.m.—Prof. C. F. Carter: "The Economic Use of Brains" (Presidential Address, Section F).

At 10 a.m.—Dr. K. P. Oakley: "Dating Man's Emergence" (Presidential Address, Section H).

At 11.30 a.m.—Dr. Richard G. Lipsey: "Can there be a Valid Theory of Wages?—A Study of Fact and Fiction in Economics" (Lister Lecture).

At 2.30 p.m.—Dr. Judith Milledge: "Form and Colour in Nature" (Darwin Lecture).

At 8 p.m.—Dr. B. V. Bowden: "The Impact of Automation" (Evening Discourse).

Tuesday, September 5

At 8 p.m.—Mr. Kenneth Adams: "Seeing in the Round" (*Eidophor* programme).

APPOINTMENTS VACANT

Applications are invited for the following appointments on or before the dates mentioned:

Research Chemist or Biochemist (graduate or postdoctoral), to pursue studies in the chemical dynamics of bones and teeth—Dr. S. A. Leach, Turner Dental School, The University, Manchester 13 (September 1).

Research Assistants (2) in Theoretical Physics at St. Salvator's College, for D.S.I.R. financed posts in support of research on difference equations, asymptotic expansions and perturbation theory, and on associated problems in theoretical solid state physics—particularly metals and semiconductors—The Secretary of the University, College Gate, St. Andrews (September 2).

Senior Library Assistants (2) (graduates with library experience), for duties in the Cataloguing Department—The Librarian, The Main Library, The University, Edgbaston, Birmingham 15 (September 8).

Assistant (graduate in botany or agriculture, or equivalent qualifications) to the Mycologist, for work involving testing the susceptibility to disease of crop varieties, present work is mainly concerned with the cereals—The Secretary, National Institute of Agricultural Botany, Huntingdon Road, Cambridge (September 15).

Lecturer (graduate in medicine, science or veterinary science preferably with a master's degree and research experience) in Physiology at the University of Queensland, Australia—The Secretary, Association of Universities of the British Commonwealth, Marlborough House, Pall Mall, London, S.W.1 (September 15).

Senior Lecturers (2) in Chemistry at the University of Nigeria, Nsukka—The London Representative, University of Nigeria, 33 Craven Terrace, London, W.2 (September 15).

Chemical Engineer, Physical Chemist or Physicist (honours graduate with at least two years research experience) in the Unit Operations Group, Chemical Engineering Section, C.S.I.R.O., Melbourne, to be engaged on either of the following projects: (*a*) a study of the dynamic characteristics and controllability of closed circuit grinding, and other solid-handling processes, using modern techniques including frequency response; or (*b*) investigations within the general field of water desalination—Chief Scientific Liaison Officer, Australian Scientific Liaison Office, Africa House, Kingsway, London, W.C.2, quoting Appointment No. 608/14 (September 16).

Senior Research Assistants (2) (preferably with qualifications in medicine, psychology or sociology), for a research project on the prescribing of drugs by doctors and the distribution of products by drug houses—The Registrar, The University, Liverpool, quoting Ref. CV/TES (September 16).

Senior Research Fellow or Research Fellow (with a Ph.D. degree in organic chemistry, with additional experience in general synthetic organic chemistry) in the Biological Inorganic Chemistry Unit, John Curtin School of Medical Research, Institute of Advanced Studies, Australian National University, to work on the synthesis of multidentate organic ligands, as part of the programme of the Unit on the effects and utilization of metal complexes in biological systems—The Secretary, Association of Universities of the British Commonwealth, Marlborough House, Pall Mall, London, S.W.1 (September 18).

Chair of Sociology in the University of Ghana—The Assistant Registrar (London), University of Ghana, 15 Gordon Square, London, W.C.1 (September 25).

Chair of Philosophy in the University of Ghana—The Assistant Registrar (London), University of Ghana, 15 Gordon Square, London, W.C.1 (September 25).

Lecturer in Solid State Physics in the School of General Studies, Australian National University—The Secretary, Association of Universities of the British Commonwealth (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, September 29).

Chair of Veterinary Science in the University of Melbourne, Australia—The Secretary, Association of Universities of the British Commonwealth (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, September 30).

Experimental Officer or Senior Experimental Officer (preferably with a degree or diploma in physics or electrical engineering; previous experience of high voltage engineering, electronics and nuclear physics would be an advantage), to take charge of maintenance and operation of a 6-MeV. electrostatic generator—The Registrar, The University, Manchester 13 (September 30).

Lecturer or Assistant Lecturer (with an honours degree in psychology and preferably research interests in experimental or social psychology) in Psychology at the University of Canterbury, New Zealand—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (New Zealand and London, September 30).

Professor of Animal Husbandry at the University of Queensland, Australia—The Secretary, Association of Universities of the British Commonwealth (London Branch), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, September 30).

Professor of Microbiology at the University of Queensland, Australia—The Secretary, Association of Universities of the British Commonwealth (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, September 30).

Lecturer in Philosophy at the University of Sydney, Australia—The Secretary, Association of Universities of the British Commonwealth (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, October 6).

Lecturer in Physiology at the University of Western Australia—The Secretary, Association of Universities of the British Commonwealth (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, October 7).

Lecturer (with a degree in science or agricultural science, with experience in research and teaching in plant pathology) in Botany at the University of Melbourne, Australia—The Secretary, Association of Universities of the British Commonwealth, Marlborough House, Pall Mall, London, S.W.1 (October 31).

Chair of Psychiatry in the University of Melbourne, Australia—The Secretary, Association of Universities of the British Commonwealth (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (November 1).

Assistant Director (with a good knowledge of helminthology in its application to agriculture) of the Commonwealth Bureau of Helminthology, St. Albans, for duties which include abstracting, editorial work and general administration—The Secretary, Commonwealth Agricultural Bureaux, Farnham House, Farnham Royal, Bucks (November 15).

Biochemist (science graduate), to carry out biochemical tests in the area laboratory—The Group Pathologist, Group Laboratory, c/o St. Thomas's Hospital, Hydestile, Godalming, Surrey).

Director (scientist with experience of research in fibre technology) of the Jute Research Institute, Dacca, Pakistan, for duties including advice to the Government of Pakistan on research on jute and other fibres; initiating and conducting research, and lecturing—The Department of Technical Co-operation, Almack House, King Street, London, S.W.1, quoting PAK/163.

Postdoctoral Research Fellow (preferably with experience in the use of gas chromatography and/or mass spectrometry), for research in the gas phase reactors of methylene—Dr. H. M. Frey, Chemistry Department, The University, Southampton.

Postgraduate Research Assistants (with a degree in biochemistry, chemistry, physiology, physics or zoology) in the Department

OF PHYSIOLOGY AND BIOCHEMISTRY—The Secretary and Registrar, The University, Southampton.

RESEARCH ASSISTANT (with a good degree in zoology, and with an interest in the physical and chemical properties of animal tissues) **IN THE DEPARTMENT OF BIOMOLECULAR STRUCTURE**, for the study of molecular structure of biological systems—The Registrar, The University, Leeds 2.

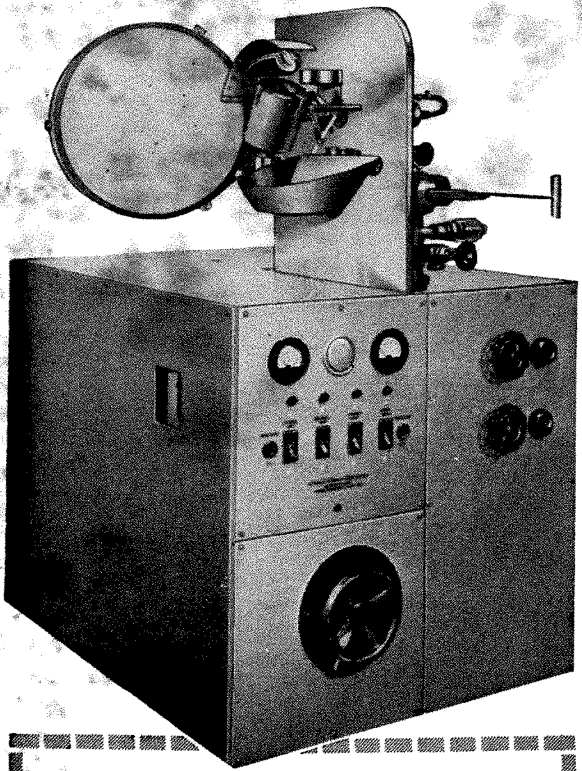
WILD BARFIELD NRC*

Laboratory Vacuum Furnace



Model 2904

2 lb. to 8 lb. capacity

(FOR OPERATION UP TO 2,000°C)

Made in Britain to the designs of the National Research Corporation of Mass., U.S.A. who have built more high vacuum furnaces now in successful operation than any other firm in the world. The Model 2904 Vacuum Furnace is a self-contained unit for high-temperature operation at high vacuum or under controlled atmosphere. It is heated by a tungsten resistance heating element with molybdenum heat shields in a water-cooled stainless steel sleeve.

This permits:

- Close control of temperature
- Good heat distribution
- Long life
- No outgassing or contamination from refractories

FOR MELTING • POURING • SINTERING
ALLOYING • HEAT-TREATING • ANNEALING

Vacuum Arc and Vacuum Induction Furnaces
Vacuum Analysis Equipment • Vacuum Diffusion Pumps

STANDARD EQUIPMENT

- High vacuum pumping system with Wild-Barfield-NRC oil diffusion pump and Gas Ballast mechanical pump.
- Metal cabinet base, overall dimensions 35″ x 43″ x 34″ high.
- Pyrex bell jar, 18″ diameter x 12″ long, protected with a wire mesh guard, or optionally a stainless steel bell jar.
- Water-cooled basin to shield the bell jar and to catch spilled metal.
- Feed-through for thermocouple wires or heater leads for special work.
- 15 kW. power supply, controlled with a variable auto-transformer. Power is supplied to the split tungsten sleeve through water-cooled coaxial leads.

* NRC *is the trade-mark of the National Research Corporation, registered in the United States Patent Office.*

APPOINTMENTS VACANT

UNIVERSITY OF ST. ANDREWS

Applications are invited for a Lectureship or Assistantship in Psychology in the Department of Psychology, Queen's College, Dundee, in the University of St. Andrews, commencing October 1, 1961, or as soon as possible thereafter. Salary scales: Lectureship, £1,050 by £50 to £1,400 (efficiency bar) by £75 to £1,850 (initial appointment in lower part of scale); Assistantship, £800 by £50 to £950. F.S.S.U., family allowance and grant towards furniture removal expenses.

Applications (six copies, naming three referees), to be lodged not later than September 7, 1961, with the undernoted, from whom further particulars may be obtained.

SECRETARY OF THE UNIVERSITY.
c/o Queen's College, Dundee.

R.R.E. COLLEGE OF ELECTRONICS

MINISTRY OF AVIATION
ROYAL RADAR ESTABLISHMENT
MALVERN

Lecturer required, owing to expansion of courses, for January 1, 1962, to teach Physics and Mathematics for Higher National Diploma Courses. Applicants should have a degree or equivalent qualification, and have teaching or other suitable experience. Burnham salary scale £1,370 by £35 to £1,550 for Lecturers; subject to the Teachers' Superannuation Acts.

Further details and application forms obtainable from the Principal for return within two weeks of the appearance of this advertisement.

AUSTRALIAN NATIONAL UNIVERSITY

CANBERRA
INSTITUTE OF ADVANCED STUDIES
DEPARTMENT OF ASTRONOMY

The University proposes to make three appointments in the Department of Astronomy (Head of Department: Professor B. J. Bok, Mount Stromlo Observatory). Each appointment will be made at one of several levels between those of Senior Fellow and Research Fellow, dependent on the qualifications and experience of the appointee. The salary ranges are: Senior Fellow, £A.3,000 to £A.3,550; Fellow, £A.2,120 to £A.3,000; Senior Research Fellow, £A.2,620 to £A.3,160; Research Fellow, £A.1,625 to £A.2,450. Superannuation is on the F.S.S.U. pattern. Reasonable travel expenses are paid and assistance with housing is provided.

A summary of conditions of appointment and descriptive papers setting out the research programme and facilities of Mount Stromlo Observatory and the Department of Astronomy, A.N.U., are available from the Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1. Applications will be considered immediately after June 1 and October 1, 1961.

UNIVERSITY OF MELBOURNE

OLYMPIC CONSOLIDATED INDUSTRIES LTD.
POSTDOCTORAL RESEARCH FELLOWSHIP

Applications are invited for the above fellowship in the Chemistry Department of the University of Melbourne. The research will be on physico-chemical investigations of the surface chemistry of organic polymers of interest to the tyre industry. The salary is in the range £A.1,250 to £A.1,500. Tenure one, two or three years. Tourist sea fare to Melbourne will be paid to an overseas fellow.

Entries should be lodged with the Dean of Graduate Studies, University of Melbourne, Parkville, N.2, Victoria, Australia, by November 30, 1961, and the Fellow is expected to assume duty early in 1962. Further particulars may be obtained from the Secretary, Association of Universities of the British Commonwealth (Branch Office), Marlborough House, Pall Mall, London, S.W.1.

COMMONWEALTH BUREAU OF PASTURES and Field Crops, Hurley, Berkshire, requires Indexer (female). Duties: indexing literature on agricultural science; proof reading; compilation of bibliographies. Qualifications: knowledge of scientific terminology; must be conscientious, methodical, and accurate. Salary in scale £443 to £989. Superannuation scheme. Age, qualifications and experience considered when fixing starting salary.—For further details and application form apply to Director. Closing date September 4, 1961.

UNIVERSITY OF MANCHESTER

TURNER DENTAL SCHOOL

Applications are invited for a research Chemist or Biochemist, graduate or postdoctoral, to pursue studies in the chemical dynamics of bones and teeth. The work in progress involves various aspects of the mechanisms of calcification and demineralization and there will be ample opportunity for an individual approach to these problems. This is a Medical Research Council Staff Appointment and the salary and conditions are similar to those of University staff of similar qualifications and experience.

Further details may be obtained from Dr. S. A. Leach, Turner Dental School, the University, Manchester, 13, to whom applications should be addressed not later than September 1, 1961.

NEW ZEALAND

SENIOR RESEARCH FELLOWSHIPS

Applications are invited for Senior Research Fellowships to be taken up in New Zealand in 1962. Applicants should possess a Ph.D. degree, or an equivalent qualification, or whilst not having such qualification have a distinguished record of scientific research. There is no age limit and no restriction regarding nationality, but successful applicants must meet New Zealand immigration requirements. A good working knowledge of English is required.

The Fellowships will be awarded for research at any of the branches of the New Zealand Department of Scientific and Industrial Research. They will be tenable for periods of between six months and one year initially, but may be extended to a total period of two years. The value of each Fellowship will range between £1,400 and £1,900 a year, with an additional £250 a year for a married man. These amounts are taxable. (£N.Z.1 approximately equals £1 Sterling.) A grant for return fares by surface transport to New Zealand is payable to each Fellow, and an allowance of two-thirds of this grant may be paid where a Fellow is accompanied by his wife. While in New Zealand reasonable travelling expenses incurred in connection with the Fellow's research work will be paid.

Application forms and further particulars are obtainable from:

The New Zealand Scientific Liaison Office,
B.C.S.O.,
Africa House,
Kingsway,
London, W.C.2, England.

The New Zealand Embassy,
19 Observatory Circle,
Washington 6, D.C.,
U.S.A.

The Office of the High Commissioner for New Zealand,
Suite 804,
Commonwealth Buildings,
77 Metcalfe Street,
Ottawa, Ontario, Canada.

The Department of Scientific and Industrial Research,
P.O. Box 8018,
Wellington
New Zealand.

Applications should reach New Zealand by November 30, 1961.

UNIVERSITY OF MANCHESTER

Applications are invited for appointment of an Experimental Officer or Senior Experimental Officer to take charge of maintenance and operation of the Manchester University 6 MeV. electrostatic generator. Previous experience of high voltage engineering, electronics, and nuclear physics would be advantageous, and a degree or diploma in physics or electrical engineering is desirable, particularly for the senior appointment. Salary scales attached to this post are: £700 by £30 to £790 by £40 to £1,000 per annum (Experimental Officer); and £1,000 by £50 to £1,250 (merit bar-line) by £50 to £1,500 (Senior Experimental Officer). The initial salary will be according to qualifications and experience. Contributory superannuation scheme.

Applications should be sent not later than September 30, 1961, to the Registrar, the University, Manchester 13, from whom further particulars and forms of application may be obtained.

METALLURGIST OR PHYSICIST WITH postgraduate research experience and preferably some knowledge of ceramics, required for fundamental research work on problems associated with welding. Excellent working conditions and facilities, attractive salary according to age and experience.—Apply in writing to Research Manager, Murex Welding Processes Limited, Hertford Road, Waltham Cross, Herts.

UNIVERSITY OF MANCHESTER

Applications are invited from suitably qualified graduates for two posts in the Department of Electrical Engineering of the Faculty of Science as Lecturer and Assistant Lecturer. Candidates should have interest in any of the branches of Electrical Engineering. The salary scales are as follows: Lecturer, £1,050 to £1,850 per annum; Assistant Lecturer, £800 to £950 per annum; initial salary and status according to qualifications and experience. Membership of F.S.S.U. and children's allowance scheme.

Applications should be sent not later than September 2, 1961, to the Registrar, the University, Manchester, 13, from whom further particulars and forms of application may be obtained. Overseas applicants should send letters of application (no forms), as soon as possible, giving details of qualifications and experience, and submit the names of at least three persons to whom reference may be made.

ASSISTANT PROFESSOR OF PHYSIOLOGY

The University of Alberta invites applications for the position of Assistant Professor of Physiology, to become effective after January 1, 1962, at a salary, depending on qualifications and experience, within the range of $6,500 to $9,200 per annum with annual increments. Duties include a limited amount of undergraduate and graduate teaching, while the new staff member will be encouraged to pursue his own programme of research. The department is interested in obtaining a staff member with some training in the field of cellular physiology but this should not exclude applicants with other special fields of interest. Inquiries for further information should be addressed to Dr. J. W. Pearce, Department of Physiology.

Applications for the above position, including a curriculum vitae, the titles of publications, a recent photograph and the names of three referees should be sent to the Dean of Medicine, University of Alberta, Edmonton, Alberta, Canada.

UNIVERSITY OF EDINBURGH

AND
SOUTH-EASTERN REGIONAL HOSPITAL BOARD, SCOTLAND
MEDICAL PHYSICS UNIT

A first- or second-class honours graduate Physicist is required to apply physics to a wide range of medical problems, initially in the radioactive isotope field. A new department at present under construction will be occupied shortly. Collaboration in joint research projects will be expected and there are ample opportunities for individual research. The salary will be in the range £730 to £1,150 per annum.

Either recent or experienced graduates are invited to submit applications, with the names of two referees, to the Secretary, S.E. Regional Hospital Board, 11 Drumsheugh Gardens, Edinburgh, 3.

BRITISH CERAMIC RESEARCH ASSOCIATION

SPECIAL CERAMICS

There are several vacancies in this newly formed and expanding Division of the British Ceramic Research Association for Senior Scientific Officers, Scientific Officers and Senior Technical Officers. A good background in chemistry and/or physics is preferred, but experience in ceramics is not essential. The work covers the development of new materials, e.g., non-oxide ceramics, inorganic polymers, refractory coatings, etc., the assessment of their properties and their potentiality in electronic components, rocketry, nuclear power and general engineering. Excellent facilities are available for this work and publication is encouraged. The posts are permanent and progressive and carry superannuation provision under the Federated Superannuation System for Universities. Salary will depend on age, qualifications and experience but will be in the range of: Senior Technical Officer, £850 to £1,150. Scientific Officer, £730 to £1,150. Senior Scientific Officer, £1,200 to £1,650.

Applications, giving details of age, qualifications and experience, should be sent to the Director, Dr. N. F. Astbury, The British Ceramic Research Association, Queens Road, Penkhull, Stoke-on-Trent.

UNIVERSITY OF LEEDS, PHARMACOLOGY Department, requires a Technician. Chemical or biological experience desirable. Salary according to age, qualifications and experience, on a scale from £490 (normally at age 21) to £675.—Apply by September 2 to Professor D. R. Wood, Department of Pharmacology, School of Medicine, Leeds, 2.

THE URGENCY OF INTERNATIONAL CO-OPERATION

IN his presidential address to the British Association, printed elsewhere in this issue (p. 977), Sir Wilfrid Le Gros Clark touches on a recurrent theme in presidential addresses to the Association since, at its centenary meeting, Smuts referred to the way in which the scientific advance of mankind had outstripped ethical development and the need to close this gap. Perhaps even more noteworthy, however, are the similarities between Sir Wilfrid's address and that on the moral un-neutrality of science which Sir Charles Snow delivered at the meeting of the American Association for the Advancement of Science early this year. There can be no such thing as the ethical neutrality of science, for by the very nature of scientific activity, the scientist, with his over-riding respect for the truth, has a built-in moral impulse that imposed on him a constant moral discipline. This, and not the æsthetic values which the scientist shared with other creative workers is what really marked off scientific activity from other intellectual activities.

Moreover, this is not the only moral component for the international character of the scientific community was evident even as late as thirty years ago. Laying some stress on the personal links which then still existed within the international work of science, Sir Charles suggested that the exchanges which took place then were, and have remained, more valuable than all the diplomatic exchanges ever invented. While this position was shattered in nuclear physics with the development of the atom bomb, much of the international community of science remains in other fields such as biology, and Sir Charles considers that the moral and intellectual leadership of science may well pass to biologists and that among them we are likely to find the Rutherfords, Bohrs and Francks of the next generation.

It is at this point that Sir Charles links up the morality of the scientists with the problems of an organized society. Only a very bold man, when a member of an organized society, has the power to say no; but, recognizing this, Sir Charles nevertheless believes that scientists have a moral imperative to say what they know. The spring of knowledge itself provides a spring of moral action in scientific activity which is at least as strong as the search for truth; and, as Sir Charles sees it, this moral imperative could supply the driving force which would enable scientists to meet their plain duty in the present world situation and explain clearly the implications of the challenge which now confronts mankind.

Sir Wilfrid Le Gros Clark arrives at essentially the same position by a very different route. Believing that the dangerous uncertainties looming ahead make it essential to take stock of the species *Homo sapiens* whose evolution has culminated in mankind to-day, he believes also that it is our duty as scientists to insist that this is a matter of quite extraordinary urgency—and to make it apparent as widely as possible. The frightening question is now beginning to present itself, whether the civilization which mankind has slowly and laboriously built up over a period of many thousands of years can avoid disastrous dissolution as the result of uncontrollable or uncontrolled struggles for political power or economic superiority; and, indeed, whether the human species can avoid at least partial extinction by the misapplication of its own ingenuity.

Sir Wilfrid begins with a rapid review of how we came to be and how we are constituted in our physical and psychological adaptability to cope with our changing environment to-day. He notes that human evolution has by no means been a record of uninterrupted, uni-directional progress, and that probably the development of the distinctively human type of social organization depended in the first instance on the use of tools and weapons in co-operative activities for foraging and hunting for food and for the protection of family groups. This demanded an accelerated development of those parts of the brain whereby emotional and instinctive impulses can be more effectively subordinated to the good of the community as a whole. It is his thesis that the emergence of the biological species *Homo sapiens* has been the resultant of selective pressures directly dependent on the invention and development of increasingly complex cultural organizations. Stressing the importance of the period of immaturity during which the growing child remains dependent on the adult members of the community, thus making possible the full post-natal development of the large and complicated brain and also providing the opportunity for educating the individual to adapt himself to the intricate inter-relationships of human society, Sir Wilfrid remarks that if man (in the broadest sense) invented culture, it was culture which invented *Homo sapiens*.

Considering now man as he is to-day, Sir Wilfrid points out that an outstanding feature of our species is a broad and plastic adaptability rather than a narrow adaptedness to some particular set of conditions. He emphasizes that our biological adaptability needs to be constantly supplemented by deliberate and conscious efforts to adapt ourselves to local circumstances as they arise. There is some reason for satisfaction, so far as physical and biological environments are concerned, in the success achieved in utilizing the resources of the physical and biological sciences and the derived technological developments, by developing more effective methods of control of pests and protection against disease and by intensive studies of the physiological and psychological factors underlying the adaptational potentialities of the human body; but the related field of ergonomics, or the study in the widest context of man in relation to his working environment, has as yet not been developed to anything like the same extent.

It could well be argued that here is to be found one important factor responsible for some of our economic difficulties to-day. Sir Wilfrid recognizes that the relevance of ergonomics to industry, so far at least as the rational design of machinery and the control of the immediate climatic working environment are concerned, is widely admitted; but the factor of adaptability enters no less into such matters as redundancy, arising out of technological change through developments such as automation and the application of computers and other electronic devices. It is a matter of the adaptability of both trade unions and of management, and is clearly a more formidable task than is presented on the material plane, where, as Sir Wilfrid observes, we can feel some assurance of ultimate success, provided adequate funds and facilities are made available for investigation by scientific methods.

Quoting John Stuart Mill's observation "There is not a more accurate test of the progress of civilization than the progress of the power of co-operation", he remarks of this question of mankind's adaptation to his sociological environment that, while there has been demonstrably a broad historical trend towards a progressive unification of mankind, this has come about as a result of conflict between opposing groups, ending in the emergence of the vanquished into the social and economic structure of the victor, as well as by mutual agreement for the furtherance of common interests. This process of unification has been to the ultimate benefit of the whole community by achieving a higher level of co-operation, permitting, for example, a more centralized organization of all means of production, more efficient control over local fluctuations in food supply, more comprehensive planning of large-scale projects of irrigation and transport and more economical division of labour. It can thus be regarded as a major factor determining sociological progress; but in these larger groups of human society, Sir Wilfrid fears that there is the basic danger that, with increasing pressure of population, the altruistic sentiments which in the course of a long evolutionary history have become ingrained in the mentality of the individual are too apt to be suppressed by the narrow interests of each particular group.

There have been some unhappy demonstrations in recent years of the way in which in Britain sectionalism works against the interests of the community as a whole; and it is undoubtedly true also that in the larger groups the attitudes and opinions of the individual come to be directed for him by all the subtleties of propaganda developed in a complex society, so that we have to face the seemingly paradoxical fact that the larger the units of co-operation in social communities the greater the tendency for their segregation into populations opposed to each other by conflicting economic and ideological interests. This has, as Sir Wilfrid observes, tended to slow up the historical process of unification and threatens to halt it; but before we question whether it is even feasible to hope for a final unification of the whole of mankind, it should be remembered that some of the difficulties at the international level arise precisely because not all members of the international community have reached the same level of culture or civilization. We cannot assume the existence everywhere of the altruistic sentiments to which Sir Wilfrid refers, and this is undoubtedly one factor that threatens world order to-day.

Nevertheless, Sir Wilfrid rightly maintains that an essential prerequisite for any attempt at further unification for the good of mankind as a whole is the ability to give full expression to the impulse for co-operation which is so characteristic a feature of the humanity of man, and that this can only be made possible by opportunities for the free interchange of ideas among the population of the world. At this point Sir Wilfrid expresses his conviction that science has a vitally important part to play. Regarding science and technology as culminating expressions of the co-operativeness on which depended the genesis of the form of human society in the past, he suggests that science is in a particularly favourable position to effect the closest contacts between peoples who may be divided by political and other interests. Thus he points to the recognition by scientists of all countries of the need to retain and develop harmonious relations, because the very advance of science depends on free communication. Secretiveness is a brake on such advance, because it prevents the unrestricted interchange and interpenetration of ideas among those engaged on common problems.

Sir Wilfrid thus recognizes this pattern of unity and co-operation among scientists even in the face of circumstances which often appear frustrating, and he asserts indeed that the quintessence of the scientific mentality is to be found in a willingness to communicate and discuss new advances in knowledge with completely open-minded freedom, uninhibited by any attempt at secrecy for partisan or sectional interests of any kind. Moreover, he finds that the universality in the logic of the scientific method permits an intimacy of understanding scarcely possible in fields of learning where there are fundamental conflicts of opinion derived from preconceived convictions and beliefs, based on unverifiable evidence and not amenable to scientific methods of inquiry by the rigorous test of repeated observation and experiment. How far this profound respect for objective truth, which may be regarded as intrinsically a self-regulating process, imposed on the scientist by the very nature of science, contributes to the promotion of a sense of toleration and intellectual humility may be a matter of opinion and is not discussed either by Sir Wilfrid Le Gros Clark or Sir Charles Snow; but there can be no gainsaying the points they make about co-operativeness being an essential element in the pursuit of science, and the responsibility of the scientist to explain the implications of advances in scientific knowledge. There may be reservations as to the extent to which international scientific associations can and do influence mankind generally, particularly in the face of national conflicts, but there can be no question as to the value of associations which are wholly international in achieving full international unity. Furthermore, even where regional research institutions and other regional institutions supplement national institutions in the study of problems of common interest, membership should, as Sir Wilfrid insists, be open unconditionally to competent scientists of any community whose welfare depends on the results of the institution's research projects.

The process of dissipating tendencies towards national rivalry and engendering an atmosphere of concord may be slow—much slower than Sir Wilfrid suggests—though he rightly points out that time is getting very short. That is not, however, to belittle the importance of scientists seeking to inculcate as widely as possible a spirit of freedom in scientific inquiry which gives full expression to the deep-rooted altruism; such altruism is an essential attribute of the humanity of man, and can possibly do much to preserve and intensify the feeling of harmony among all peoples of the world. It is rather that it strikes a fresh note of urgency in the task, particularly where it involves also fostering similar altruism among some of the less-developed and emergent nations. A concrete objective is, in fact, set before the British Association, and also associations of professional scientists and technologists, namely, to make plain, in season and out, to the individual citizens and the communities to which they belong, the probable impact on everyday life of new scientific and technological discoveries. This involves demonstration of the principles and methods of scientific inquiry by which discoveries have been made, with the inferential corollary that the same principles and method can also be applied, with some assurance of success, to other outstanding problems of a similar nature. Whether or not there is still time to complete the task, it is essential that it should be undertaken wholeheartedly and urgently. Full co-operation by all scientists of all races is essential; they should address themselves to the study of those specific problems in ergonomics and other fields which bear on co-operation in industry and in society, and the way men and women live together in communities in an era of rapid and often bewildering technological change.

VERTEBRATE PHYLOGENY

Théories de l'Évolution des Vertébrés

Reconsidérées à la Lumière des Récentes Découvertes sur les Vertébrés Inférieurs. Par Erik Jarvik. Préface et traduction du Prof. J. P. Lehman. (Monographies Scientifiques.) Pp. 104. (Paris : Masson et Cie, 1960.) 20 N.F.

IN the University of Stockholm at about the turn of the century, when the Department of Zoology acquired new premises they renamed it Zootomiska Institutet. This was to emphasize that the zoology studied there was not 'mere systematics', but the science of the detailed and comparative structure and development of animals; and perhaps nowhere has research been so faithful to this ideal. What has especially appealed to the Stockholm school is the development in ontogeny and phylogeny of the rhythmic plan of vertebrate segmentation and encephalization. While Holmgren, Pehrson and others made their discoveries on the living species, Stensiö and his school have been able to test the conclusions based on comparative anatomy and embryology by direct anatomical studies of fossil vertebrates.

The technique invented by Sollas—grinding and photographing, grinding again and photographing, until the specimen is destroyed, leaving a record of its structure from which wax models can be made—has been used to such effect by these dedicated workers that we know more about the detailed structure of some of the early chordates than about many a living species.

Stensiö's first work of this kind, on *Cephalaspis* (1927), was a great event. I remember his lectures on the subject at University College, London, when in deliberate, matter-of-fact tones he said of this palæozoic animal: "And so, you see, we are forced to the conclusion that this animal possessed a functional pronephros".

Jarvik, himself a distinguished contributor to this work, has written a little book summarizing such results of these many studies as have had most influence on our interpretation of the relationships of the classes and subclasses of lower vertebrates, and on the course of evolution within the series.

We have come to accept that the cleft between lampreys and hagfishes, based largely on the naso-hypophyseal relationships, represents the palæozoic cleft between Cephalaspidomorphs and Pteraspidomorphs, as Stensiö concluded in 1927. The discoveries on the Placoderms have not yet been incorporated into our text-books. Parker and Haswell in their *Text-book of Zoology* (Forster-Cooper's edition) too hastily accepted the conclusion of Watson that the Acanthodii possessed a ventral hyoidean gill-slit. Anyone acquainted with a range of Teleostean forms would know that the presence of a single row of gill-rakers on the ceratohyal was no argument for this, and Holmgren pointed this out in 1941 with additional evidence against Watson's theory. Stensiö has found both Arthrodires and Antiarchi to have a great deal in common with the Selachii, so that he unites them broadly as 'Elasmobranchiomorphi'. No one has yet used the Sollas technique on an Acanthodian, so this group is dismissed by Jarvik as *mal connu*.

Jarvik lays much emphasis on the results of his own work on Crossopterygii, which, he concludes, were already divided into two groups ancestral to Anura and Urodeles respectively. This conclusion is based mainly on the structure of the snout, analysed in detail in his work of 1941–42. It is an example of the way in which the new work has pushed divisions back further, so that the dotted lines of the phylogenetic tree, which once joined to form a main trunk, now vanish back into the unknown. On the other hand, Jarvik has allowed himself a theoretical tree in which, with the help of a few hypothetical groups, there are no dotted lines at all.

Uniformity of basic plan is re-emphasized, and one of the most interesting and elegant results is the inclusion of the dermal bones of the base of the skull in the segmental pattern of the visceral arches. *Latimeria* does not receive extended mention partly because this book is a kind of supplement to the corresponding parts of the *Traité de Zoologie*, where this Cœlacanth receives adequate attention; but perhaps partly too because Millot and Anthony wrote their first fine volume on its anatomy without disclosing the condition and course of the profundus nerve, a great disappointment to the Swedes, since it has an important bearing on the interpretation of the homologies of the pre-mandibular somite.

The concept of de-lamination (why not supra-lamination ?) and the lepidomorial theory, the use of the course of the lateral-line canals rather than the pineal to determine the homologies of the roofing bones of the skull and the abandoning of the theory of a wide osteogenic influence of the neuromasts, are acceptable generalizations which seem overdue. The origin of the paired fins by concentrations of originally broad-based segments of the fin folds receives new support from Stensiö's work on the Arthrodires in which (*mirabile dictu*), as in the Cephalaspids, the course of nerves, arteries and veins was preserved as hard encasing tubules. But the opposing theory quoted (to be demolished) by Jarvik, that the two paired fins were formed by the growth behind two of the spines of the ventro-lateral series in *Acanthodes* of a web, rays, muscles, etc., is cruder than any which I have ever come across.

The Swedish original of this timely and challenging book is one of a score of articles in *Svensk Naturventenskap 1959*, year-book of the Swedish national council for research in the natural sciences, and the translation was published without giving Dr. Jarvik an opportunity to equip it for its new purpose. Necessarily condensed and somewhat arbitrary, it drives the reader for evidence to the original papers, yet lacks a bibliography. The absence of an index is partly compensated by a good list of contents. There are few misprints (a full stop where there should be a colon in the middle of p. 31 is an awkward one). The many illustrations, including photographs and colour-diagrams, probably account for the expensiveness of this handsome paper-back, which should nevertheless be studied by every serious student of vertebrate morphology and phylogeny.

To most of us the French version is very welcome, but anyone with a reading knowledge of Swedish would have a bargain in the original, well bound, with two additional colour-plates of Jarvik's models and a number of articles on diverse subjects, all for the much lower price of 18 Swedish crowns.

E. TREWAVAS

SOCIAL HISTORY OF ENGINEERING

A Social History of Engineering

By W. H. G. Armytage. Pp. 378. (Faber and Faber, 1961.) 42*s*.

PROF. ARMYTAGE'S volume is the first of a series which, we are told, is designed primarily for candidates for the diploma in technology, but also for the professional scientist and engineer. The dust-jacket also tells us that the series "has been planned to help the specialist take account of the economic, social and political implications and consequences of his work and influence in society at large". Books written to this recipe are of course badly needed. The history of technology, edited by Dr. C. Singer, aroused great hopes which the published volumes have not wholly fulfilled. Their bulk and cost alone would have made them unsuitable for use by the large numbers of young men interested in the subject, or compelled to study it.

For the success of this new series the present volume augurs neither badly nor well. Books like this must serve two distinct objects—to provide a factual record of technological development in the past and to relate the development to changes in society. The two tasks require from the author a combination of aptitudes and of equipment not commonly to be found together; and it would not therefore have been surprising or unforgivable had Prof. Armytage succeeded in one of his tasks better than in the other. But this is not what Prof. Armytage has achieved. He has come within sight of both his objectives, yet the distance by which he has failed to reach either would be sufficient to damp the enthusiasm of the most indulgent of reviewers.

As a historical record the book suffers from an excess of that very quality against which Prof. Armytage warns us in his preface, that is, packaged history. Technical facts, scientific and engineering terms follow each other at the double quick. There are about 1,200 proper names in the index, and this contains only some of the names which pepper the pages. Moreover, it is precisely because he tries to tell so much that he often fails to tell us enough. Lack of space has prevented him from explaining the nature of many of the inventions and innovations and processes which he enumerates, with the result that some of the pages would be largely incomprehensible to an average student, be he even a student of technology. Now and again, Prof. Armytage is compelled to compress his facts to the point of distortion. His story of the improved harnessing of animals in the Dark Ages is told as if it concerned the replacement of oxen with horses, whereas its main achievement was greater efficiency in the use of oxen. The introduction of the open-field system in the same period is described as if it originated in the eighth century and was all organized on a three-field system from the outset. To pass to the other end of the spectrum, Prof. Armytage refers to *Zeta* as if it were a technical success, and credits Prof. Jewkes with a proposition concerning the contribution of large firms to inventions, which is exactly the opposite of the views which Prof. Jewkes is commonly believed to hold.

For the same reasons, Prof. Armytage is sometimes compelled to gloss over the technical trends which, if brought out, might have introduced order and coherence into his story of individual inventions. Thus, the technological progress in European mining is described as if it began with certain vague improvements in the 1450's. The reciprocal connexions between technical innovations in the textile industries of the eighteenth and the early nineteenth centuries receive no more than a passing reference; the linked developments in agricultural engineering are scarcely mentioned. The story of aircraft between the Wars leaves the reader unaware of the process whereby in the early thirties there emerged the first monoplanes with stressed skins, retractable undercarriages and monocoque structures. The story of radar glosses over the scientific and technical developments which proceeded and followed Watson-Watt's initiative, and there is scarcely a word in the book about Appleton, Oliphant or Roe. In the story of engineering proper nothing is said about progressive changes in working speeds and tolerances and the consequent evolution of machine tools, or about cigarette-making machinery, scientific instruments or watches and the part they played in the development of precision and automatic tools.

Much of the book's space is of course given over to non-technological matter brought in to supply the social background. Some of these data are highly relevant and valuable. Prof. Armytage's account of technical education, his story of the higher engineering schools abroad, and above all, his account of the connexions between individual engineers, who worked with whom, who established the nurseries of engineering talent, how and when the engineers began to collaborate and the professional institutions were established—all this had never been brought together so briefly and so conveniently as Prof. Armytage has done in his book. This alone would justify his effort and commend it to the general body of interested readers.

Unfortunately, the same cannot be said about many of the other non-technological facts in the book. A history of technology linking it with economic conditions, social changes and intellectual movements is something which, in the present state of the literature on the subject, no single person could be expected to conjure up; and Prof. Armytage is certainly no conjuror. The only social correlation he is able to establish at all convincingly is that of war. He has no difficulty in showing how successive wars stimulated progress in applied sciences, and above all in engineering. But many of his other correlations appear to be questionable or irrelevant. What, for example, has the destruction of drainage at Passchendaele got to do with technological changes ? How does Mr. Hollerith's tea-time conversation with Dr. Billing, who had some twenty years previously collected statistics on the Army of the Potomac, establish the connexion between the American Civil War of 1861 and the invention of the Hollerith system in 1890 ? What has the enforced sales of British securities in America in the two World Wars ("led to increasing dependence on the American stock market") got to do with technological change in the same period ? Modern architecture may or may not be part of the recent history of engineering, but if it is, its history does not begin with Gropius; and even if it owed as much to Gropius as Dr. Armstrong believes, why insist on Gropius's fleeting connexions with A. E. G. and yet fail to give an adequate account of the Bauhaus. I do not believe that a writer as pressed for space as Prof. Armytage need have bothered to bring in the Indian Mutiny, but if he did, he might have taken care not to make the Moslems venerate the cow and the Hindus abhor the pig.

These are mere examples culled at random, but they should be sufficient to explain why the reviewer's verdict is bound to remain open. The book contains some valuable information, conveniently summarized for the discriminating reader, but it cannot be recommended as a sole guide for young men about to be examined in the social history of engineering.

M. Postan

UNIVERSITY SELECTION

The Chosen Few

An Examination of some Aspects of University Selection in Britain. By W. D. Furneaux. Pp. xxvii + 245. (London: Oxford University Press, 1961. Published for the Nuffield Foundation.) 25s.

DISCUSSION on educational topics seems to go in cycles. After a spate of discussion, both informed and uninformed on the selection of children for secondary education and a number of published researches on the reliability, validity and sociological consequences of such selection methods, it is now the turn of the universities' selection procedures to be closely scrutinized. These provide a more formidable task for the investigator; the fewer university bodies with their particular faculty requirements are often less co-operative than the 146 local education authorities with their eleven-plus selection procedures. As the author of the present book points out, this lack of co-operation is often not deliberately so, but is due to the lack of availability of records and information about students who are accepted or rejected for a university course.

This research began in 1948 under the auspices of the Nuffield Foundation and was carried out by the Nuffield Student Selection Unit of the University of London Institute of Psychiatry. Access to relevant records was not granted by Oxford and Cambridge, and the main research was centred on the University of Sheffield. There is no evidence to show that this restriction provided a satisfactory sample of university entrants. One point does emerge clearly; unless each university endeavours to build into its selection scheme some follow-up measure of the trustworthiness and validity of its selection methods, the continued wastage of time and talent will continue. Interviewing candidates as a selection instrument is still as unreliable as it was found to be by Hartog and Rhodes in their report in 1935. With increased number of university applicants and the correspondingly greatly increased wastage of time by university staff in considering applications, alternative psychological methods will have to be considered and tried out. As Furneaux says of the academic staff responsible for selection: "In general they set about their work conscientiously and with devotion, but are guided by a mixture of empiricism, tradition, and personal experience, which cannot always be expected to produce the most valid results".

According to the author, 'A' level results constitute "the only reasonable and available objective evidence", but these results do not reach the selection panels early enough and even then, because of the difficulties of assessing the value of 'essay-type' questions, are not very efficient predictors. It is pointed out that the main function of 'A' level results is to confirm "that the minimum statutory entrance requirements have been complied with"; however, the recent report by J. A. Petch does show that the General Certificate of Education examination has some predictive value. One rather gathers that preliminary acceptance of a student by a university owes a great deal to the skill shown by the headmaster in the writing of his report, nevertheless, Furneaux believes that more use might be made of these headmasters' reports, if the universities would use a more precise method such as a questionnaire for eliciting relevant information.

This report underlines all the known difficulties of student selection and criticizes, at least by implication, the waste of time and effort on students' multiple university applications; it points out that there seems to be no clear evidence that the standards achieved by students admitted to a university and those applicants who were rejected by this university and admitted to another, differ in any marked way.

Points raised in Part 1 of this study relate to multiple applications, sociological background of students as a determinant of selection and wastage of talent. Part 2 deals more specifically with the Nuffield investigation. This is a useful source book, though finding one's way through the various facts and arguments, often repeated and expanded in various sections of the book, is not too easy even with the help of the index; this may be due to the ten-year time-lag between the initiation of this study and its final publication. However, few will disagree with the main points of the author's thesis, and his plea for some form of clearing-house system is timely.

Psychologists and sociologists will look forward to the second volume, and now that Mr. Furneaux has dealt with the background of selection he will be free to deal with the ways in which psychological tests and procedures can be of use in university selection.

W. H. KING

THE PHYSIOLOGY, PHARMACOLOGY AND PATHOLOGY OF MUSCLE

The Structure and Function of Muscle

Edited by G. H. Bourne. Vol. 2: Biochemistry and Physiology. Pp. xiv + 593. 118*s*. Vol. 3: Pharmacology and Disease. Pp. xiv + 489. 107*s*. 6*d*. (New York: Academic Press, Inc.; London: Academic Press, Inc. (London), Ltd., 1960.)

THIS treatise on muscle is completed by the present volumes. In Volume 2, the first two chapters, on the chemistry of myofibrillar protein and on the biochemistry of muscular action, set a high standard. Chapter 3 gives an account of the biochemistry of muscle mitochondria, and is followed, in Chapter 4, by an essay on endocrinology with reference to muscle. Chapter 5, entitled, "The Neuromuscular Junction: Role of the Acetylcholine System", is a discursive review of some aspects of conduction, neuromuscular and synaptic transmission. Chapters 6 and 7 give a concise account of the biophysics of muscle, and are followed, in Chapter 8, by an excellent survey of the comparative physiology of the activation of muscle. The next two chapters are essays on human muscular physiology, with emphasis on factors limiting performance and on fatigue. Chapter 11 is a full and balanced review of the central nervous control of skeletal muscle, which covers the substantial advances made in the past two decades. This volume is concluded by a stimulating chapter on certain aspects of the physiology of cardiac muscle.

It is regrettable that much space has been given, in Volume 2, to marginal topics, such as endocrinology and the biochemistry of sarcosomes, apparently at the expense of an adequate treatment of the physiology of smooth and cardiac muscle. A disappointing feature of the book is the section on neuromuscular transmission, which unduly emphasizes the personal views of the author. Fortunately, these faults are offset by the uniformly high standard of most contributions to this volume, which can be recommended to the advanced student and teacher as a useful account of many of the recent advances in the biochemistry and physiology of muscle.

In Volume 3 two chapters are devoted to pharmacology: Chapter 1 is a review of the actions of drugs on smooth and skeletal muscle; in Chapter 2 some aspects of the effects of drugs on the myocardium are discussed. Virus infections involving muscle are described in Chapter 3, which is followed by a chapter on the parasitic infections of muscle, with emphasis on the widespread prevalence of sarcocystic infestation. An illustrated account of the degeneration and regeneration of skeletal muscle in Chapter 5 is succeeded by chapters on the effects of nutritional deficiencies on muscle, and on the histological changes in muscle due to ageing. Chapter 8 is an authoritative review of recent advances in the study of post-mortem changes in muscle, with especial reference to rigor mortis. The histochemistry of muscle is dealt with in Chapter 9. The pathology of the intrinsic diseases of muscle is described in Chapter 10, which is followed by a chapter on the clinical features of these diseases. Chapter 12 is an interesting discussion of the genetic aspects of muscular disease. A brief but stimulating essay on some fundamental problems of muscle biochemistry concludes the work.

The article on the pharmacology of skeletal and smooth muscle is outstanding, in Volume 3, in its conciseness, and will be of great value to the general reader. It seems remarkable that, in the treatment of pathology, parasitic and virus infections are considered in some detail, but no mention is made of Clostridial infections. The quality of the histological illustrations is not uniformly satisfactory: many are too small and suffer from poor definition. Nevertheless, this volume may particularly interest clinicians, and should focus attention on a field which has hitherto been rather neglected. D. H. SPROULL

ECTO- AND ENDO-PARASITES OF SOUTH-EAST ASIA

Malaysian Parasites

XXXV–XLIX. Edited by W. W. Macdonald. (Studies from the Institute for Medical Research, Federation of Malaya, No. 29.) Pp. vii + 251. (Kuala Lumpur: Institute for Medical Research, 1960.) 9 Malayan dollars; 21*s*.; 3 U.S. dollars.

THIS is the third volume of a series of collected papers on the ecto- and endo-parasites (including biting insects and arachnids) occurring in south-east Asia. It contains two long papers, both by C. B. Philip and W. W. Macdonald, on Tabanidae and Culicinae respectively, a review of the host distribution of Malayan ticks by J. R. Audy and others, and several shorter papers on mites, together with one on the rearing of ixodid ticks and another on nematode parasites of domestic rats.

Like its predecessors it is well bound, clearly and attractively printed and illustrated, and remarkable value for money. Most of the papers are for the expert, but Macdonald's paper on the ecology of mosquitoes in lowland dipterocarp forest should interest the general reader. The same author's paper on *Armigeres* sub-genus *Leicesteria* also contains much of ecological interest, with particular reference to the fauna of bamboo internodes.

It is sad to think that most of those who worked in the Institute during the publication of this series have now dispersed. Their achievements bear witness to the unique potentialities of a team of this kind. The present staff can be trusted to carry on the tradition within the limits of their resources. For the rest it is to be hoped that visiting experts will use the Institute as a centre for exploring the marvellously rich fauna of south-east Asia and the many intricate and still little understood problems of human ecology which the area presents.

P. F. MATTINGLY

ART AND THE ENGINEER*

By PROF. MISHA BLACK, O.B.E.

School of Industrial Design (Engineering), Royal College of Art,
London, S.W.7

NEGLECTING the massive contrary evidence, many engineers continue to console themselves for a lack of creative ability by assuming, and constantly reiterating, that form inexorably follows function and thus that a solely scientific or technological approach to engineering produces forms which are visually so satisfactory as to eliminate the need for conscious æsthetic endeavour. The protagonists for this view point with pride to high-speed passenger aircraft as proof of their theory, and extend the range of their evidence by mustering the hulls of ships, the control rooms of power stations, electronic equipment and the mechanism of intricate machinery to their support.

One must reluctantly counter these admirable bids with the lamp standards which still destroy the visual amenities of a thousand streets, most rail and road bridges built since 1900 and the myriad consumer and capital products which have gone far towards destroying the pleasures of city life and have eroded the rural scene.

This balancing of the good against the unsuccessful would be an amusing game if the stakes were less than our total environment, which they in fact represent.

Thus I am producing these over-simplified arguments which before now should have been transferred to a more serious level of discussion. Those who might be expected to represent the opposing views have long past composed their differences. Sir Herbert Read (whose loyalty to the arts is unquestioned) wrote in 1934[1]: "One false theory assumes that if the object in question performs its function in the most efficient way possible, it will *ipso facto* possess the necessary æsthetic qualities. To this argument we must reply that an object which functions perfectly may, and probably will, possess æsthetic qualities, *but the connexion is not a necessary one*".

The late Oscar Faber (whose engineering experience is beyond dispute) said in 1944 (in a paper delivered at the Institution of Civil Engineers)[2]: "The fallacy, which is very widely held, is that if a structure is honestly designed to satisfy all its scientific or engineering requirements it will of necessity be beautiful . . . all I can say is that I wish it were true, because most engineers can design a structure scientifically with a constant factor of safety in all its component parts, and if that were a guarantee that the result would be beautiful the problem would indeed be a simple one. Unfortunately, all that one can say about it is that such a structure may by chance be beautiful, but it will only be by chance". Yet at every conference on civic or industrial design the ancient ritual is repeated, and at least one engineer can be relied on to chant the now venerable refrain that form automatically follows function, that mechanical efficiency produces its own art form and that association with the arts is advisable only outside the drawing office and workshop.

This dogmatism on the part of some engineers has sustained the equally emotional opposition of humanitarians. They, from William Morris onwards, imagining their values threatened by developing technology, have retreated (as the forces of science are too virile and powerful for open battle) historically into the peaceful backwaters of arts and crafts and to-day into art forms which express their own despair and have meaning only for those who understand their obsessive pessimism.

The continuing vigour of the argument results from there being right on both sides. There is no doubt that the engineers of the twentieth century have produced the most memorable symbols of our time which, when examined in the perspective of future centuries, may well prove to be more important manifestations of our then past than all but a few of the more self-conscious works of our architects, sculptors and painters. But it is equally true that the majority of the works of our civil and mechanical engineers are characterized by a mediocrity only equalled by the mass of our architecture. The engrossing mystery is the unevenness of quality which can be found in the work of even a single homogeneous group of engineers, the circumstances which make it possible for the designers of a superb flying machine to produce cabin interiors redolent of a shoddy suburban hotel and for the designers of an efficient and economic street lighting system to mount the fitting on poles whose only excuse is that others are yet more disagreeable.

At the Frontiers of Knowledge

The answer to this inconsistency lies in the extent to which the engineer is working at the frontiers of knowledge. When the problem set is more technically exacting than any attempted before in that field, then the discipline of the problem, the need to probe beyond existing boundaries of knowledge, produces formal results which exactly mirror the period of history which made that technical development possible. They thus have a quality of exact correctness which is classically satisfactory. Because it was produced at the advanced headland of a civilization, it could only be materialized by men who were, for that moment, at the head of their time and through them their society expressed one aspect of its greatness. Such work crystallizes the essence of a period and, on a subsidiary plane, is comparable with the fine arts which similarly express a society annealed through the fire of a single personality.

Because such work is done at the frontiers of experience its result may not always be generally comprehensible, especially in periods of revolutionary transformation, but during the post-industrial revolution period, which is my concern here, the gap of time between achievement and public acceptance has progressively decreased. Thus to-day the creative jump forward which produced the *Caravelle* jet aircraft required no period of gestation before it was accepted as a proud symbol of the first year of this decade.

---

* Substance of a lecture delivered at Hatfield Technical College on June 23.

An appreciation of this view is obscured by the problem of early steps ahead into undeveloped technological ground when the creative probes produce unresolved intermediate solutions which appear primitive and immature in comparison with the then fully developed earlier forms which they are destined later to supersede. For example, one may remember the primitive forms of the early steamships as poor cousins to the then still extant majestic sailing vessels, the tottering early aircraft and the first motor-cars a parody of their future.

But though at times the early forms of a new technology may seem beautiful only to the enthusiast, the basic fact I think remains. Form follows function when the form is that of objects or mechanisms which are at the height of their time when the need to resolve scientific and technological problems exclude all other considerations and when the consciousness of the engineers is completely absorbed within the superhuman task of reaching ahead into the then unknown.

The purity of design which is possible in such circumstances is, however, a rare occurrence. It is hindered by the necessity for its expression at a stage of technological development which allows for mature solutions, it requires, in mechanical engineering, the opportunity for development of a completely new product instead of the more usual modification to part of an existing object or mechanism, and it postulates a problem being attempted in which the needs of human usage are of secondary importance. To this last point I shall return, but first may I complete this part of my argument by re-stating that engineer-designed objects of the type I have been describing possess an intense emotional content. If all the artefacts of our society were produced in this way, the problems we are considering and the need for this article would not exist. But they are not. The vast majority of engineering projects and products are conceived well within the boundaries of scientific knowledge and technological experience; the developments in a new project are commonly marginal—a minor step forward. In such engineering undertakings the possible variations multiply and usually reach infinity. Here conscious judgment, choice and constant decision face the engineer, and in these decisions æsthetic choice plays, as I hope to demonstrate, a major part.

The Clue to Confusion

Here is the clue to present confusion. The engineer rightly sees that the major 'break-through' works possess great beauty, and he is sometimes arrogant enough to believe that the qualities of great achievement must automatically be reflected in his more pedestrian daily tasks. He does not, in this context, accept the common knowledge that quantity affects quality, and that what operates satisfactorily at one scale does not necessarily do so when the scale is greatly increased or diminished. The beam which properly bridges a 20-ft. span should not simply increase in size when the span increases to 200 ft.—and the reverse is equally true. The engineer developing a motor-car which is only a stage in advance of last year's model is not operating at the frontiers of knowledge; the electronic engineer reducing the depth of a television tube is similarly working at a lesser pitch; the designer of a gas cooker or a Diesel locomotive is also operating at a level where application is more appropriate than vision. At this, the normal daily working level, the differences in design of objects produced to the same general performance specification demonstrate the freedom of choice which exists, within, of course, controlling technical conditions.

This is, I believe, indisputable. It is a truism which only the strange lack of its appreciation justifies repetition. I do not under-estimate the importance of the controlling factors of materials, manufacturing processes and cost; but these provide only the matrix within which other motives also determine the engineering decision. In domestic appliances the plethora of refrigerators and washing machines, for example, indicates how wide is the choice which faces the engineer even when the technical requirements have been established with reasonable exactness. The varieties of kettles, automobiles, vacuum cleaners and Diesel locomotives reveal major differences in ease of operation and of appearance which cannot be explained only by variations in specification or production facilities.

The engineer is a decision-making animal, and it would therefore be useful to examine the motivators of his decisions.

Motivators for Decisions

I believe that the majority of engineering decisions, within the boundaries of technical facility, are made from emotional and seemingly inconsequential premises. The radio engineer arranges the controls of a television set in relation to the screen mainly because he thinks 'it looks better that way': the draughtsman selects a particular form for a domestic radiator because he prefers that form to any of the thousand alternatives that exist within the specification of his task. The final appearance of a modern machine tool is as much the outcome of these proliferating individual æsthetic decisions as was the form of a nineteenth-century beam-engine elaborated with the Grecian columns and the cast-iron filigree which the engineer of that time similarly considered the appropriate (if then less inhibited) æsthetic decision.

This concern of the engineer with æsthetics, with the appearance of things, is now firmly established. It manifests itself in a desire for neatness, for invisible fastenings, for the compact and orderly disposition of units. It works towards the attainment of an elegant engineering solution in which the most simple economic solution is commonly jettisoned for one which has required difficult development to effect the elegant solution as efficiently and as economically as the more immediately obvious brash commonplace one.

During the past fifty years, however, a disturbing element has been introduced into this technological development towards what Whitehead[3] has called "... the most austere of all mental qualities ... the sense of style". The serious searching for the most fitting solution is now commonly influenced by a real or supposed knowledge of market requirements, and engineers have been known to reject both the commonplace and the elegant solution for one which is neither in order to satisfy their sales staff, who are convinced that only falsification and bogus elaboration will be acceptable to their markets.

If it is accepted that the engineer commonly makes æsthetic decisions, it is reasonable to ask whether he is fitted to do so. The answer must certainly be that he is only sometimes so fitted. I have already excluded the pioneer design projects from this consideration as almost unconsciously determining their own form, but for the rest the ugliness which excretes over our streets and homes, offices and workshops is a disquieting reminder that all is not yet well. For this the engineer is not to be blamed. He has been educated, as have people as a whole, with almost complete disregard for the cultivation of any visual sense—he has had little experience in producing or appreciating the visual arts. He has been encouraged to develop his eyes into acquisitive organs concerned only with selecting for conscious recognition those aspects of the world which are of material benefit to him. He has learned to see a lamp-post to avoid bumping into it, but not to see the lamp-post so that he knows and takes pleasure or offence from its shape.

Perceptive vision has been succinctly described by Suzanne Langer[4]: "What we see in this way becomes simply a thing of vision—a form, an image. It detaches itself from its actual setting and acquires a different context". The engineer has been given little, if any, training in the technique of looking and seeing, of the minute examination of objects, or in the sense of touch and the co-relation between visual and tactile sensations.

Slowly that situation is changing as the importance of art in general education is gaining recognition, but the average graduate engineer is still visually untrained, still partially blind and then finds himself, in that twilight of cataract, faced with the need constantly to make æsthetic, formal, visual, three-dimensional decisions. In this situation the surprise is not that so much is second rate, but that so much achieves satisfactory visual standards.

A Cure for Blindness

A cure to this problem could theoretically be found in an adjustment to the curricula of engineering students which corrected the faults of their primary education and imbued their time at university or college of advanced technology with the humanities. These human studies, it has been argued, could be biased towards the visual arts so that the graduate engineer became able to make more expertly those æsthetic decisions which must later constantly confront him.

This could satisfactorily deal with the problem if it were not for two at present insurmountable difficulties. First, the knowledge required for a primary engineering degree can only be mastered by application to essential studies which leave no time for a still further extended curriculum. There is already insufficient time after basic theory has been taught to allow for the development even of primary engineering design and for application to the technique of making decisions based even on purely factual information and specification. Secondly, the present too early division of boys and girls into scientific and humanistic specialization tends to dissuade from the scientific stream those very students who might be able to assimilate a degree course in which the arts are co-ordinated with the sciences.

The immediate answer must be found, I believe, in the training of a special type of engineer who, from the commencement of his technological education, is encouraged to concentrate on that aspect of engineering which is now commonly absent from the curriculum. He must be what in our civilization is considered to be an odd character, part engineer, part artist. He must have a feeling for form analogous to that of the sculptor or architect, he must be aware of the emotive effect of colour, he must be sensitive to the tactile qualities of surface, and, at the same time, he must be able to draw and calculate, to talk to mechanical and production engineers in their own terms and on their own ground. He must be sensitive to the society he serves, conscious of the movements in public taste, excited by problems of ergonomics and anthropometrics.

If he were all these things in full measure he would be a superman, the impossible Leonardo da Vinci of the twentieth century. But I am not, of course, suggesting a course of training for supra-engineers. My aim is more modest. Those undergraduates whose training is emphasized towards what the Americans call 'human engineering' are only partial Leonardos. Alone they are useless and even dangerous in their superficiality, but teamed with those whose training and experience have been differently directed towards technological specialization, they can provide the link between technology and humanity, between those who design the machines and those who use them.

A start has been made. A few art schools and technical institutes in Great Britain are now experimenting with training of this kind. This training is still in the elementary stages in which the instructors are groping for the teaching techniques which will achieve their known objectives, which will produce graduate engineers who can complete the production team.

The Industrial Designer

A title must be found for this comparatively new specialization, which has so far reached a degree of maturity only in the United States. There they are called 'industrial designers', and that name, with all its obvious limitations, must serve as an internationally accepted nomenclature. It is more fitting, by its very ambiguity, than the German '*Formgeber*' or the French '*estheticien industriel*'.

If we accept the need for such specialized technicians, the 'missing technician' as John Gloag called him in 1945[5], it would be useful to consider how he can best function in the industrial complex. To this, as to every question in which technology directly affects human needs, there is no simple positive answer. The answer shifts its position as circumstances change.

In the design of capital goods, machine tools, special duty machinery, locomotives and industrial electrical equipment, the industrial designer's function should be a minor one. He should be a watchdog for the operator, a worrier about detail, an expert in anthropometrics and ergonomics; he should be concerned with problems of calibration, communication and psychological well-being. He should be concerned also with finish and maintenance, with the form of the total machine so that its appearance reflects the excellence of its mechanical operation. In such cases the industrial designer is no more than the guide dog of a gifted blind man. His function is essential, but it is subservient to the needs of his master, the engineer.

In consumer products the emphasis shifts. In the design of a typewriter the human needs of the typist are as important as the mechanical efficiency of the machine. The assembly of the keyboard, the shape of the shift key, and ease of operation, become vital factors in the total design. The appearance of the machine becomes a vital element in its acceptance, and the work of the industrial designer begins to equal in importance that of the designer of the typewriter as a printing machine.

In domestic appliances the emphasis shifts still further into the territory of the industrial designer; into the strange world of consumer acceptance and product death-dates, where what the housewife will or will not like in her kitchen, what the marketing division believe they can and cannot sell, reach heights of monumental irrationality. This is a hinterland of personal preferences and peculiar dislikes, of motivation which often has but little to do with the real value or efficiency of an appliance. It is a publicity-aggravated dreamland in which the industrial designer is able to function, sustained by training and experience which have steeled him to its vagaries, and from which he can produce a reality which can materialize the highest standards society will accept instead of, in despair, looking for the lowest common denominators.

Style, Design, Obsolescence

The reservations of an engineer when asked to accept an industrial designer as a colleague are understandable. They arise first from the human weakness which suspects that this new appointment is a criticism of his own ability. This is a comparatively simple problem of human relationships which time will help to resolve. An aeronautical engineer does not question the advisability of working with a stress engineer, or with experts in hydraulics, electrics and other branches of intense specialization. Few architects doubt the wisdom of collaboration with civil engineers; few surgeons would be prepared to operate without an anæsthetist.

The other cause for lack of enthusiasm for collaboration is more serious. It arises from the engineer's deep distrust of the whole operation of industrial design. He suspects that the designer is concerned purely with superficial style, with fashionable frippery which is completely separated from, and sometimes detrimental to, the function of a mechanism.

At its most extravagant this design concept is expressed in some automobile design in which the body-work is disagreeable and in which spear-pointed exuberances turn an innocent vehicle into a lethal pedestrian-hating weapon. It is expressed in kitchen equipment which is so loaded with gadgets as to require the housewife to turn herself into a skilled mechanic (or to disregard the elaborations which she has expensively bought), and which is a pleasure only to the service engineer who is kept busy repairing this unnecessary complexity.

But having properly disparaged such baroque styling, the need for style remains.

To reduce the problem to its essential crudity: 'things are made for people'. Human needs, desires and ambitions must be the arbiters of all industrial production. There is no gain in manufacturing an excellent piece of equipment which no one needs or wants and is therefore not prepared to buy. This is a truism for any society as soon as the earnings of any large section of the community exceed their minimum requirements for shelter and food. It is already manifest in the U.S.S.R., where the increasing supply of 'non-essential' consumer products such as television sets is creating the problems of consumer demand or resistance which have for long been a characteristic of Western marketing. This sensitivity to human needs and the relation of the form and operation of engineering products to the style which mirrors each facet of a society at each moment of its complex and uneven growth is an attribute of the skilled industrial designer; it is one of his specialized functions.

The reasons for the disrepute of this quite proper function, about which the industrial designer is as sensitive as the engineer is scornful, is that too often the body-work of industrial products has been 'styled' by self-styled designers whose talents reside only in their ability to produce competent perspective sketches which satisfy the uncritical judgment of industrial management and, often, disregard all production and servicing desiderata. This process has become self-propagating as the engineering staff have always managed to find a method of producing the stylist's extravagances; a sufficiently large market has been satisfied by these monstrous objects which has become status symbols and, in the competitive battle for markets, the gadgetry of one manufacturer has been capped by another's still wilder bid for applause and profit.

The situation remains with us; but the tide shows signs of turning. The industrial designers are becoming serious and expert. They have largely renounced the extravagant showmanship which was their defence during the period when their battle for recognition was more bitter than it now remains. They are being trained to collaborate with their colleagues in the factory production team and are no longer expected by industry to produce magical rabbits at the drop of a commission. They are as concerned with production problems as are the production engineers themselves; they have willingly discarded their artist's freedom for the discipline of the factory, hopeful that serving a social purpose will compensate for the compromise this almost inevitably imposes.

Scientific Romanticism

I want, lastly, to consider an aspect of this problem which inhibits an appreciation of it in what I believe to be a proper perspective. Those designers who have accepted their essential liaison with science and industry have sometimes transformed what should be understanding and sympathetic friendship into too passionate a love affair. To quote from a recent issue of the Italian publication *Zodiac*[6]: "The important art of the twentieth century is going to be produced by the men who understand our age and who create artistic objects which are useful to-day. Those men who create these objects are the true artists of our time". In his fundamental book, *Art and Industry*, Sir Herbert Read wrote: "Such beauty as we admire in Greek vases, and in the undecorated forms of Mediterranean art generally, can undoubtedly be produced by machinery".

I wish that I could accept these adulations of the industrial designer. It would be pleasant to believe that a stainless steel coffee pot made by the hundred thousand in a Midlands factory could have the same quality as one of Isaac Dighton's silver pots of the early eighteenth century. But the mass-produced pot, however appropriate and satisfying its proportions may be, however well it may be made, however efficiently it may operate, however good the quality of its metal and finish, lacks the one quality essential to a work of art. It lacks uniqueness. That is a quality which every natural organic object possesses: it is the quality which every hand-made artefact possesses, it is the quality which in great works of art gives them a distinction which justifies man as a creator, as a god on earth.

That quality exists in the original model which the engineer and the industrial designer may together produce, but it must be ironed out and tooled away so that the machine may produce its thousand copies without the stigmata of individuality which would make a mockery of the very process of industrial production.

In almost completely obliterating uniqueness the machine obliterates humanity in its production. The formal mathematical qualities of form and proportion remain, the sense of pleasure in using an efficient object remains, positive satisfaction in handling a well-made thing exists, but these are not, in themselves alone, the qualities of a work of art.

For compensation, we have the multiplication of machine production. If the æsthetic quality of a motor-car cannot equal that of even a minor sculpture by Henry Moore, the faint æsthetic pulse in the dehumanized forms of the automobile is multiplied by the number of cars made from the same mirror-polished tools. In quantity the mild æsthetic pleasure each car evokes adds up to an important factor in our daily lives. Multiplied by the million objects of our environment, their effect on our lives begins to equate with the impact of a single work of art.

All the works of all the designers for mass production cannot equal one Rembrandt self-portrait or a Cézanne still-life, but that need not deny us a modest satisfaction in producing, if we eventually do, an environment in which, against our machine-created background of neutral and agreeable objects, the painters and the sculptors and the architects and the great engineers can produce their masterpieces.

COAL IN OXFORDSHIRE

By Dr. C. J. STUBBLEFIELD, F.R.S., and Dr. F. M. TROTTER

Geological Survey of Great Britain

THE Geological Survey of Great Britain[1] has implemented a programme of boring during each year since 1948. The programme is undertaken independently of the investigations carried out by national boards, industrial concerns and private bodies; and the purpose of the boreholes is to obtain a fuller knowledge of the geology of Great Britain. Should raw materials of commercial value come to light from this work, the information concerning them is made available to the public so that other organizations, if they so desire, may explore further and exploit them.

In order to preserve a balance between short- and long-term research, in some years it has been the Geological Survey's policy to drill shallow boreholes so that that knowledge of the sub-surface geology may be increased in areas covered by 1-in. maps which at the time are being officially surveyed geologically. In other years boreholes are planned for use in long-term investigation of the underground geological composition and structure in extensive areas of Britain covered by Mesozoic rocks and to check the results of geophysical researches; in general these are deeper boreholes.

Among the several regional studies now in hand, one concerns the nature of the sub-Mesozoic rocks in the area between the Severn basin and Oxford. In this area two exploratory boreholes—both were less than 2,000 ft. in depth—had been made in earlier years by industrial concerns; the first of these boreholes was started in 1872 and finished in 1875 at Signet, Burford (National Grid Reference 42/251101); strata classified as Coal Measures were entered at 1,174 ft. and boring continued in them to a depth of 1,409 ft. (ref. 2). The borehole was stated to have encountered a coal seam at 1,350 ft., but its thickness, presumably less than a foot, was not recorded and no samples of strata were kept. The second borehole, 15 miles farther north at Batsford, Lower Lemington (Nat. Grid Ref. 42/215346), was started in 1901 and completed in 1904; beneath Triassic rocks at 1,021 ft., it passed through Coal Measures for 525 ft. and then traversed Silurian mudstones to 1,700 ft., at which depth boring stopped[3].

The first Geological Survey borehole in this area was started in 1949 at Stowell Park (Nat. Grid Ref. 42/084118) about ten miles west-north-west of Signet, Burford[4,5]. This borehole confirmed the existence of a deep basin of Mesozoic rocks underlying the Cotswolds and the Vale of Gloucester, and drilling stopped in 1951 at a depth of 4,503 ft. without the base of the Mesozoic (Triassic) rocks sequence being reached.

The Geological Survey then turned its attention nearer to, and slightly north-west of, the site of the 1872–75 Signet borehole. Boring commenced in 1952 at Upton, Burford (Nat. Grid Ref. 42/232131). The Upper Coal Measures were reached beneath the Triassic rocks at a depth of 1,107 ft. (733 ft. below Ordnance Datum) and were proved to a thickness of 2,660 ft.; a few thin coal seams were found, but owing to technical difficulties the bore stopped at a depth of 3,767 ft. in July 1953[6,7].

For some years the area between the Severn and Oxford had been the subject of gravity, magnetic, and limited seismic surveys by the British Petroleum

Co., Ltd.[8], and although the Geological Survey[9,10] announced its intention in 1955 that boring might be continued at a site or sites progressively eastwards from the Cotswolds, its borehole activity there was deferred for some years pending the results becoming known of future boreholes by the oil company in that area. The first of these, a borehole drilled in 1955 at Faringdon, Berkshire (Nat. Grid Ref. 41/323940)[11,12], revealed Lower or Middle Old Red Sandstone (Devonian) rocks beneath Triassic at a depth of 2,150 ft. (1,852 ft. below O.D.) and another borehole drilled in 1958 for the Gas Council at Noke Hill (Nat. Grid Ref. 42/539129)[12] five miles north-north-west of Oxford found Upper Old Red Sandstone underlying Mesozoic rocks at about 380 ft. (66 ft. below O.D.).

When these results became known and no further boring by the British Petroleum Co. seemed likely in the early future, the Geological Survey started a borehole in August 1960 at Apley Barn, north-north-east of Witney Park (Nat. Grid Ref. 42/344107)[13].

The surface-level is 280·1 ft. above Ordnance Datum and the borehole commenced in the Great Oolite White Limestone. Various subdivisions of the Jurassic were proved, including the Marlstone Rock-bed (the top of the Middle Lias), which was 1 ft. 9 in. thick with the base of the bed at 171 ft. 9 in. In passing it may be noted that the Marlstone Rock-bed worked for ironstone north-west of Banbury at a thickness of about 20 ft. has thinned at Witney, as it does farther north towards a north–south line through the Vale of Moreton and the Vale of Bourton. The base of the Jurassic was found at 564 ft. and that of the Rhætic at 592 ft. 8 in.

The base of the Keuper Marl was penetrated at 760 ft. 6 in. and the sandstones below have been assigned to the Keuper Sandstone. Reddened Upper Coal Measures underlie the Keuper Sandstone without visible unconformity, thereby rendering difficult the fixing of the demarcation line; provisionally the base of the Keuper Sandstone is taken at 820 ft. 10 in. Reddening of the Upper Coal Measures persists to a depth of 927 ft. The first seatearth type of mudstone was encountered at 907 ft. and the first coal seam, 4 in. in thickness, at 1,005 ft. 9 in. Between 1,000 ft. and 1,948 ft. twenty coal seams were proved, and in this account these measures, which are principally mudstones, may conveniently be termed the Uppermost Coal Group; the total thickness of coal found in this Group was 21 ft., including one 3-ft. seam of coal with its base at 1,661 ft. 6 in. From 1,948 ft. to 2,602 ft. dominantly argillaceous measures included mudstones with ironstones, seatearths and four thin coal seams; in these strata, red, brown, purple, yellow, green and variegated measures alternated at about 20–50 ft. intervals with strata that were essentially grey, and these measures are called for convenience the Coloured Measures Group. These coloured relatively barren measures were underlain by 270 ft. of grey mudstones with subordinate sandstone bands to 2,872 ft. and they contained eleven coal seams and associated seatearths; these measures are here referred to as the Second Coal Group. The total thickness of coal in the Second Coal Group is 20 ft. 9½ in., and worthy of mention are a 2 ft. 7 in. seam at 2,644 ft., a 3 ft. 2 in. coal (including a 1-in. parting) at 2,689 ft. 8½ in., a 3-ft. coal at 2,749 ft. 3 in. and a 2 ft. 9 in. coal at 2,818 ft. 9 in.

The Second Coal Group is underlain by arenaceous strata of Pennant sandstone aspect which nevertheless contains eight coal seams; these measures are here called the Arenaceous Coal-bearing Group and the total thickness of coal in this Group is 14 ft. 2½ in. Particularly noteworthy are a 6 ft. 1 in. seam at 3,633 ft., of which the bottom 4 ft. 11 in. are coal, and a 6 ft. 4½ in. seam at 3,786 ft., of which the bottom 4 ft. 9 in. are coal. The base of the Arenaceous Coal-bearing Group is taken at 3,968 ft. 7 in. Fossil plants and non-marine lamellibranchs have been collected at intervals between 841 ft. and 3,773 ft., and a fish tooth at 3,943 ft., all indicating Upper Coal Measures age. A pulmonate gastropod was found at 877 ft. and in British Coal Measures such forms have been previously found only in the Keele Beds, which are the uppermost Coal Measures in North Staffordshire, and in the Coal Measures of Upton, Burford. The sequence between 2,872 ft. and 3,968 ft. contains sandstones of a type known in the Pennant Measures of Bristol and Somerset, and South Wales.

No evidence of older Carboniferous rocks was found in the borehole, for underlying the Arenaceous Coal Group is a Conglomerate Group comprising multicoloured sandstones, breccias and conglomerates with subordinate purplish and green mudstones; between 3,971 and 4,596 ft. Devonian fossils were found, including a coral, crinoid stem columnals, brachiopods and fish scales; between 4,511 and 4,562 ft. the flora indicates Middle or Lower Devonian age. Boring ceased at 4,942 ft.

The stratal gap between the Keuper and the Upper Coal Measures and that between the latter formation and the Devonian are not associated with discordance of dip. The highest dip recorded in the Devonian is 4°.

It has now been shown that coal occurs in seams of workable thickness beneath Apley Barn, and the quality of these seams is being studied by officers of the National Coal Board. Thus the name Oxfordshire Coalfield gains the significance which it lacked when E. N. Arber was criticized for coining the name in 1916 (ref. 14), on the evidence of the Signet Burford borehole, where no coal of workable thickness had been found.

The economic potentialities of the coalfield are as yet unproved. The completion of its exploration would be a lengthy procedure which is not the responsibility of the Geological Survey of Great Britain, though that organization would give geological advice if requested. A series of further boreholes would be required, and if these proved good-quality coal seams at a workable depth over a sufficiently wide area, then only might the need arise for the siting of a colliery shaft. Such a site would most probably be chosen near a railway line and Oxfordshire, like Kent, would have its concealed coalfield.

Applied Anisotropic Elasticity

R. F. S. HEARMON

The scope of the book is indicated by the chapter headings : Fundamentals; Elastic Constants and Symmetry; Elastic Constants of Single Crystals, Sheet Materials and Polycrystalline Aggregates; Some Simple Stress Systems; Stress and Strain Distribution; Wave Propagation; Anisotropic Plates. Its aim is to collect hitherto very scattered information, including Soviet contributions, as an introduction for students, research workers, designers, and others interested in the field. *Half-tone plates* 35*s net*

Chemical Crystallography

AN INTRODUCTION TO OPTICAL AND X-RAY METHODS

C. W. BUNN

No previous knowledge of crystallography on the part of the reader is assumed here, and the book deals with the use of the principal crystallographic methods—morphological, optical, and X-ray—for the identification of crystalline substances and the determination of the precise arrangements of atoms in crystal structures. For this edition it has been expanded to cover important recent developments in the various methods of structure determination. *Half-tone plates and text-figures* *Second edition* 60*s net*

INTERNATIONAL SERIES OF MONOGRAPHS ON PHYSICS

The Principles of Nuclear Magnetism

A. ABRAGAM

The purpose of this book is to give a consistent description, on a unified basis, of the various aspects of nuclear magnetism. Emphasis throughout is on clarity and rigour rather than on the abundance of factual and bibliographical data. The outlook is mainly theoretical, but a large amount of experimental evidence is included. *Illustrated* 84*s net*

Hydrodynamics

A STUDY IN LOGIC, FACT AND SIMILITUDE

GARRETT BIRKHOFF

This is a complete revision of the first edition of ten years ago. The author has brought up to date the results of further activity in the field of hydrodynamics, added a chapter on turbulence, and expanded the work on paradoxes and modelling. *Frontispiece and figures* *Second edition* 42*s net*

PRINCETON UNIVERSITY PRESS

Tools of the Astronomer

G. R. MICZAIKA and WILLIAM M. SINTON

This volume gives a guide to the instruments used in astronomical research today. Visual refractors, bifilar micrometers and meridian circles, and the new equipment of the modern solar observatory and radio astronomy are described. 62*s net*

THE HARVARD BOOKS ON ASTRONOMY: HARVARD UNIVERSITY PRESS

Ripple Tank Studies of Wave Motion

W. LLOWARCH

The author describes improvements that he has made in ripple tank technique, and deals with all aspects of the properties of wave motion which are likely to be encountered at school level, and in the earlier years of a degree course, in pure or applied physics. He also illustrates and discusses the basic properties of waves in general and their use to interpret the wave-like behaviour of sound, light, and other forms of radiation. *Text-figures* 15*s net*

THE TRAINING OF BIOCHEMISTS

UNTIL comparatively recently most biochemists in Great Britain had received their early training in other disciplines such as chemistry, physiology or medicine. However, the rapid progress of biochemistry during the post-war period has been paralleled by an increase in the number of biochemistry departments within British universities, and it is likely that most of our future research biochemists will graduate from these departments, having followed courses leading to the honours B.Sc. degree.

It is probably true to say that no one is yet certain, to the point of dogmatism, as to the best way of training such biochemists, and this no doubt reflects the position of biochemistry as a 'meeting-point' of so many other disciplines. In order to create discussion and thought on this topic the Biochemical Society held, during the afternoon of July 13, a colloquium on "The Training of Biochemists". The colloquium, which formed part of the four-hundred and eighth meeting of the Society, was held in Oxford under the chairmanship of Dr. K. S. Dodgson and was attended by more than 250 members and guests.

One of the principal controversies of the proceedings centred around the contributions of the first two speakers. Prof. S. V. Perry outlined the growth and development of biochemistry in Britain and stressed the value of the three- or four-year B.Sc. honours course in the training of the biochemist. Such courses were now firmly established in their own right and provided not only an intellectual challenge but also a sound basis for education in its broader sense. In contrast, Prof. B. Spencer suggested that biochemistry was more fitted to be a postgraduate subject, and illustrated his point with detailed reference to the systems in use in most American universities. Some lively discussion followed these contributions and although the weight of opinion was perhaps loaded in favour of the undergraduate course it was clear that most people, recognizing the important links between biochemistry and other disciplines, felt that other pathways by which biochemists emerged should remain open. Prof. R. A. Morton reiterated from the floor that the educational aspects of a university course should not be neglected in favour of 'training'. Biochemistry as an undergraduate subject was intellectually stimulating, and courses should always include aspects hard enough to stretch the mind of the student. What matters is the spirit of the course rather than the factual content.

The views of industry regarding the training of biochemists were outlined by Dr. W. F. J. Cuthbertson, who pointed out that industry as a whole was still not fully aware of the potential value of the trained biochemist. He suggested that a group should be formed, composed of representatives from academic life, industry and the various industrial research associations, to determine the contribution that biochemical graduates could make in industry, their present level of employment and the possible future requirements for them. In noting the differences between research in industry and in universities or research institutes, Dr. Cuthbertson suggested that industrial research was in some ways more exciting and variable. The freedom of academic research was sometimes illusory, and the academic research worker soon realizes that certain projects and methods of approach are more likely than others to attract financial aid to research. Most large industrial concerns exhibit a liberal attitude towards research, and the industrial biochemist is usually free to work on anything he choses providing that he can persuade his authorities to supply the necessary facilities. The training that was appropriate to the industrial biochemist was not markedly different from that followed by most university departments, but additional attention might be given to special facets such as microbiology and the use of statistics. The ability to present an account of his work in unambiguous simple English was perhaps even more important for the industrial biochemist than for his academic friends, because many of his findings may have to be assessed by people with little or no training in his own discipline or, for that matter, in any other scientific subject.

After some preliminary sparring with questioners, Dr. Cuthbertson was challenged outright as to whether industry was satisfied with its biochemical recruits. In reply he said that, generally speaking, expanding university departments and research institutes were skimming the cream of the graduates and a more encouraging attitude to industry from within university departments would be welcomed. Several speakers suggested that industry was perhaps responsible for any unfavourable attitude which might exist and, in particular, the use of graduates as 'superior technicians' by industry was deprecated. This unwelcome development certainly appears to be on the increase, and reflects the present shortage of trained technical assistants—a situation which technical colleges in Britain should be given every encouragement to ameliorate.

University and departmental entrance requirements were discussed by Dr. Margaret Kerly, and the meeting was greatly indebted to her for the work she had done in collating so much diverse and scattered information. In biochemistry, perhaps more than any other subject, opinions as to the school background appropriate to students vary considerably. Dr. Kerly pointed out that the number of sixth-form students from any one school who were interested in a biochemical career varied from none to 2 or 3 only, and it was therefore unrealistic to expect schools to modify time-tables in order to cater for potential biochemists. Time-table problems usually resulted in sixth-formers taking chemistry, physics and mathematics for advanced level General Certificate of Education, in which case they were weak on the biological side, or alternatively, chemistry, physics or mathematics and a biological subject, in which case they tended to be weak in either physics or mathematics. A possible solution might be the introduction of a new advanced level subject which combined those sections of the present physics and mathematics courses which are most necessary for all biologists.

In spite of the Biochemical Society's recent pamphlet, *Careers in Biochemistry*, inquiries in schools had convinced Dr. Kerly that many science masters and sixth-form students were only vaguely aware of the potentialities of a career in biochemistry. More propaganda will be needed in schools if more good candidates for biochemistry are to be forthcoming. Further support for this contention came during discussion, and it was suggested that individual departments could and should do more in this respect, particularly in the light of the shortage of biochemists which Britain is now experiencing.

In describing the recently revised four-year biochemistry course at Oxford, Prof. D. D. Woods stressed the importance of adequate background teaching, particularly in chemistry, but pointed out the need to introduce biochemistry at an early stage in the course in order to stimulate student interest. Experimentation in biochemical research is steadily becoming more sophisticated, and recent trends have emphasized the more biological aspects of the subject. The early introduction of such topics as cell physiology and genetics is therefore an important feature of the course at Oxford, and the Biochemistry Department was particularly fortunate in having the co-operation of other departments in the teaching of such topics.

Much interest was expressed in the course at Oxford, particularly from the point of view of its breadth of outlook, although it was clear that Oxford with its resources was in a particularly favourable position to overcome time-table problems which so beset smaller departments.

In the final paper, Dr. E. M. Crook discussed the M.Sc. course in biochemistry which has been in existence for some years at University College, London. Dr. Crook suggested that a good deal can be said for not attempting to teach biochemistry as an undergraduate subject, but a major disadvantage in adopting this attitude, so far as the course at University College, London, had been concerned, was that few M.Sc. candidates have learned any biochemistry, even of the most elementary kind, before entering the course. Moreover, a first-class honours graduate in, for example, chemistry has to be exceptionally strong-minded to proceed to an M.Sc. course in another subject in the face of the psychological impulse to go on at once to prove himself as a research worker. The danger, therefore, is that the M.Sc. course may tend to attract the less-able student who may look on the course as a means of 'upgrading' a relatively poor initial degree. On the whole, however, it seems likely that postgraduate teaching must increase. Various departments could, between them, provide a formidable series of postgraduate courses of different specialist nature, and this could prove of great value in strengthening the subject in Britain.

In summarizing the proceedings, Prof. F. C. Happold confessed himself to be out of sympathy with the title of the colloquium. We were not concerned with the training of biochemists as one trains circus animals but with their education. The latter embraces the former but it is also more difficult to achieve. In any event, those departments which already had honours courses in biochemistry were certainly not proposing to abandon them. Such courses were an excellent education in themselves providing that sufficient time was available to do the job properly. In his own opinion the four-year course appeared to be particularly satisfactory from this point of view.

Judging from the conversations which followed the closing of the meeting, the original aims of the colloquium in stimulating thought and discussion had been successfully achieved. The Biochemical Society hopes to publish the proceedings of the meeting, in monograph form, at an early date.

K. S. DODGSON

NEWS and VIEWS

New President of the British Association : Sir John Cockcroft, O.M., K.C.B., C.B.E., F.R.S.

SIR JOHN COCKCROFT, Master of Churchill College, Cambridge, and part-time member of the U.K. Atomic Energy Authority, has been elected president for 1962 of the British Association for the Advancement of Science. That year, the annual meeting will be held in Manchester.

As is well known, Sir John has achieved world-wide fame as an atomic physicist. He was Jacksonian professor of natural philosophy in the University of Cambridge during 1939–46. His first researches, beginning in 1924 at Cambridge, were concerned with the heating of transformer coils, and later, at the Cavendish Laboratory, he carried out work on the deposition of surface films by atomic beams. Later, with Kapitza, he designed much of the equipment used in the production of intense magnetic fields. In 1932, with Walton, he had devised the arrangement by which nuclear disintegration by artificially accelerated particles was first observed. He was a prime mover in the development of equipment and the erection of buildings for which the physicists at Cambridge must now be grateful. During most of the Second World War period he was chief superintendent of air defence, Research and Development Establishment, Ministry of Supply, and then became director of the Atomic Energy Division, National Research Council of Canada, during 1944–46. He was then appointed director of the Atomic Energy Research Establishment at Harwell.

Such is the high esteem in which his work is held that Sir John has been or is a member of many scientific and advisory organizations and he has been the recipient of numerous State, academic and other honours. Among the most recent are the 1961 Atoms for Peace Award, which was established as a memorial to Henry Ford and his son Edsel, consisting of a gold medal and 75,000 dollars, and the chancellorship of the Australian National University, Canberra.

Norwich and its Region

VISITORS to Norwich will find *Norwich and its Region* a very pleasing work. (Pp. 224. Norwich: Local Executive Committee of the British Association for the Advancement of Science, 1961. 15*s*.). It provides a most informative survey of the region of Norfolk and north Suffolk. The survey opens with a concise account of the historical events which have moulded East Anglia. To-day it is in the midst of a second industrial and agricultural revolution. Though to some it may appear a quiet backwater, residents are conscious of the mounting pace at which it is being drawn relentlessly into the main stream. The second section deals with geology, physiographical features, climate, and the nature of the soil. Results of recent research are emphasized. In fact, advances in knowledge of the Pleistocene deposits have been so rapid during the past few years that the authors feel obliged to point to the interim character of the account they give. The biological background of the area provides the theme for another section. Despite the extent of agriculture, much natural vegetation is still preserved. The county is actively concerned with conservation of Nature. About three-quarters of the British flora abound in Norfolk, due to the climatic contrast coupled with differences in soils. The county is rich in non-marine Mollusca; the coast, however, provides little shelter for marine animals.

The fourth theme deals with the influence of man on the environment. Physical anthropology, archæology and social, political and religious history are discussed. East Anglians are proud to be individualists, ever loath to follow the accepted pattern. From very early times, social services were instituted for the care of the sick and poor, and opportunity for schooling has not lagged behind that in the rest of England. Norfolk has a record of independence and enterprise in education no less than in farming. The final section gives a detailed informative account of the economy of the area to-day. Primary industry, like agriculture, forestry and fishing, is discussed; so too is the growth of manufacturing industry and commercial and professional services. The authors of these surveys are to be congratulated, since their natural emotional involvement with the various topics is never allowed to distort their scientific objectivity. The photographs are numerous and excellent. There is a very good map of the region. The photograph on the back cover is exquisite—a golden splendour of barley. That the book has been sent to members in advance of the meeting is to be welcomed.

Anatomy at Oxford :
Sir Wilfrid Le Gros Clark, F.R.S.

Sir Wilfrid Le Gros Clark retires from the chair of anatomy in the University of Oxford at the end of the next academic year. He is probably the last in the line of the great medical men who have been able to combine a career in anthropology, in which he is among the most distinguished of its leaders, with that of an equally distinguished career in neuroanatomy. His classical work on the nuclei and connexions of the primate thalamus, his work on the visual and olfactory systems and many other parts of the brain have shown that he is equally as good at noting the morphological changes which follow controlled experimental procedures as in descriptive anatomy. His book, *The Tissues of the Body*, is a masterpiece of lucid writing and probably the best introduction to human biology which has yet been written. In this book he shows that anatomy is the science concerned with the organization of the living body and how this is achieved during embryonic, post-natal and adult life. It must embrace the whole range of organic structure, the organization of the elementary components of living matter into cells, cells into tissues, tissues into organs, organs into systems, and systems into integrated creatures. He, like Woollard before him, urged that the teaching and study of minutiæ of topographical anatomy are an unjustifiable burden to those training to become doctors, for nowadays no potential physician, surgeon or clinical scientist can afford the time to master more than a few of the details offered by any one of the basic medical sciences, least of all those of no intellectual or even practical value. This is not to deny, however, that anatomical details are of great importance to surgical specialists, but it is by them that they should, and can most easily, be taught.

Prof. G. W. Harris, F.R.S.

Sir Wilfrid's successor will be Prof. G. W. Harris, the distinguished neuro-endocrinologist, who is at present Fitzmary professor of physiology in the Institute of Psychiatry in the University of London. Prof. Harris started his professional career in anatomy at Cambridge, where he taught for eight years and where he laid the foundations of his endocrinological research work. The electors, in choosing Prof. Harris, have shown boldness and imagination. Although, at present, he is by title a professor of physiology, he should make a most worthy successor to Sir Wilfrid, for he, like Sir Wilfrid, is interested in structural organization. For example, he has demonstrated in a series of elegant experiments that the pituitary gland (adeno-hypophysis) only operates normally when it lies in the pituitary fossa. It is not sufficient that the gland, when transplanted elsewhere in the body, remains structurally intact. Only when it is returned to the site in which it originally developed (that is, lying close to and having direct vascular relationships with the hypothalamus) does it again function normally. This work is a perfect demonstration of the importance of structural organization in relation to functional requirements, and alone suffices to indicate that Prof. Harris is well suited to develop the science of anatomy at Oxford, the foundations of which have been so well laid by Sir Wilfrid. An appointment of this kind underlines the current feeling in medical educational circles that instruction in any form of detailed topographical anatomy will have to pass into the hands of surgical specialists, as indeed it already has in some medical schools.

Visit of Russian Scientists to Harwell

As a result of the agreement recently signed between the U.K. Atomic Energy Authority and the Russian State Committee for Utilization of Atomic Energy for Peaceful Purposes, a party of five Russian scientists visited England during July 20–30 to discuss fundamental solid state physics. In order to allow the Russians to see a good cross-section of British work, the Atomic Energy Authority invited a number of university scientists to attend discussions at Harwell on radiation damage, electronic and magnetic properties of solids, and on neutron diffraction. The party also visited physics and metallurgical laboratories of the Universities of Reading, Oxford and Cambridge. The visit afforded an opportunity of learning a little about the nature and scope of work carried out at some of the Russian research institutes. It is clear that substantial results in the fields of inelastic neutron diffraction and electron microscopy of thin films may be expected in the next few years, following a marked expansion in Russian efforts in these topics which started in 1959. The Russian party was led by Prof. V. E. Ivanov, of the Physico-Technical Institute of the Ukrainian Academy of Sciences, whose main interest lies in the field of purification of metals, and included Prof. N. F. Pravdyuk, of the Kurchatov Atomic Energy Institute, Moscow, who spoke on radiation damage; Mr. V. I. Bykov, of the Obninsk Physico-Energetics Institute, who spoke on neutron diffraction; Mr. B. B. Baturov, of the State Committee for Utilization of Atomic Energy, whose main interest is in nuclear reactors; and Mr. A. D.

Sokolov, of the State Committee for Utilization of Atomic Energy, whose main interest is in particle detectors and instrumentation for physics experiments.

U.S. Nuclear Power Projects

THE third edition of *Fact Sheets on U.S. Nuclear Power Projects* is a complete revision of the sheets first published in December 1958 and revised in June 1960 (Pp. iii+51. New York: Bozell and Jacobs, Inc., 230 Park Avenue, 1961). The reactors listed are classified by coolant. The water-cooled reactors include five pressurized and eight boiling-water reactors. The sodium-cooled reactors comprise two moderated and two fast-breeder reactors, and one organic-cooled and three gas-cooled reactors are also listed. The introductory article discusses the approach to nuclear power development in the United States which has not been, and is not, aimed primarily at producing kilowatts, but is designed to develop technical information for the construction of commercial plants by the electrical utility industry. At least 133 investor-owned electricity companies in the United States of America are actively engaged in civilian nuclear power projects, including plants in operation; under construction, or under contract, or planned; or in study, research, and development projects; a complete alphabetical reference list of the projects is given at the end of the *Fact Sheets*.

New Hope for African Wildlife

GREAT concern has been felt in recent years about the accelerating rate of destruction of wild fauna, flora and habitat in Africa, without regard to their value as a continuing economic, scientific and cultural resource. It is feared that by 1970 several of the largest land mammals in Africa will not survive in a wild state. The smaller wild creatures are already under constant threat as the New Africa expands and demands on its natural resources grow. At the 1960 Warsaw Congress of the International Union for the Conservation of Nature it was recognized that the crux of the problem is to persuade the people of the New Africa to appreciate the value of their wild life not only in relation to the growth and prosperity of their country but also for the sake of future generations. It was at this Congress that the African Special Project was planned in three stages: (1) survey of problems; (2) conference to discuss possible solutions; (3) operational work to implement the solutions. Stage 1, which has already been completed, consisted of a survey carried out in sixteen African countries. Stage 2 has been planned and prepared in detail. The conference on "The Conservation of Nature and Natural Resources in Modern African States" will be held in Arusha, Tanganyika, during September 5–12. It is organized jointly by the International Union with the Commission for Technical Co-operation in Africa. For practical reasons the number of delegates had to be limited, but will include representatives of 25 governments. A number of 'fellowships' has been provided so that selected Africans of the younger generation can participate. Further information can be obtained from the Press Officer to the Arusha Conference, Ian S. MacPhail, 20 Belgrave Square, London, S.W.1.

Recent Map Publications by the Ordnance Survey of Great Britain

ON August 1, the last six sheets were published by the Ordnance Survey of Great Britain, completing the Seventh Series of the One Inch to One Mile Maps, and for the first time the whole of Great Britain is covered by a single series of maps at this scale, in which all sheets are similar in projection, size and style. The six sheets are: Sheet 1, *Shetland Islands* (*Yell and Unst*); Sheet 2, *Shetland Islands* (*North Mainland*); Sheet 3, *Shetland Islands* (*Lerwick*); Sheet 4: *Shetland Islands* (*South Mainland*); Sheet 188, *Torquay*; Sheet 190, *Truro and Falmouth*. At the same time, six publications of the new post-war series of One Inch Tourist Sheets have been published: *North York Moors ; Peak District ; Wye Valley and Lower Severn ; Lake District ; Lorn and Lochaber ; Loch Lomond and the Trossachs*. With the exception of the sheet *Wye Valley and Lower Severn*, where relief is depicted by contours and layer tints, the sheets in this series show relief by various combinations of layer tints and hill shading, which give an immediate impression of ground shapes even to the inexperienced map reader. In other respects, the style remains generally the same as that used for the One Inch Seventh Series. Copies of all sheets are available in three styles from all Ordnance Survey agents and H.M. Stationery Office bookshops (Tourist Sheets: paper flat, 5*s*. ; paper folded in covers, 7*s*. ; mounted on linen in covers, 9*s*. Seventh Series: paper flat, 4*s*. 6*d*. ; paper folded in covers, 5*s*. 6*d*. ; mounted on linen in covers, 7*s*. 6*d*.).

Problems of Psychology

A NEW quarterly journal (*Problems of Psychology*, Nos. 1 and 2. Pergamon Press, 1960) aims at publishing a selection of papers in translation from *Voprosy Psikhologii*, the Russian psychological journal founded in 1955. Dr. N. O'Connor, who is acting as translation editor, states in his foreword that he hopes to choose papers which will be both representative of Soviet psychology and at the same time of special interest to English readers. The present issue contains papers on a wide variety of topics, ranging from the role of the cerebral cortex in the perception of flicker to the psychology of a man with prodigious powers of memory. Of particular interest to English psychologists is Dr. E. N. Sokolov's extremely ingenious probability model of tactile perception. Although rather uneven, this new psychological journal will be widely welcomed.

The Royal Scottish Museum

THE annual report of the Royal Scottish Museum (Pp. 29. Edinburgh: Royal Scottish Museum, 1961), Edinburgh, for 1960 will be the last to appear under the control of the present director, Dr. D. A. Allan, for he retires shortly (see *Nature*, August 12, p. 648). The report indicates progress in all directions especially as regards the carefully planned building operations. The lecture-theatre block approaches completion, fluorescent lighting has been installed in the store rooms, and a further series of exhibition galleries have been redecorated in what is now regarded as the standard colour scheme. Considerable progress has also been made on paper with the replanning of the north-east and north-west wings facing Chambers Street. The introduction of automatic stoking and thermostatic control has led to difficulties in securing adequate humidity, but further experiments to remedy this are being carried out. The consequent diminution in work, dust and dirt in the basement storage is marked and welcomed. As usual, temporary exhibitions have been a valuable feature in the activities of this Museum, and a total annual attendance of nearly 357,000 testifies to the place of this institution in the life of the community and with visitors to the City. The director and his staff continue their valuable connexions with other cultural bodies, not only nationally but also internationally, and Dr. Allan has reason to be well satisfied with the present state of the Museum which he has directed with such conspicuous success.

Aids to Agriculture and Horticulture in Northern Ireland

The Ministry of Agriculture in the Government of Northern Ireland has produced a series of leaflets giving advice to those concerned with the raising of crops and animals. The leaflets are practical, clearly written and would be of assistance to nurserymen, gardeners and farmers managing large or small farms. One hundred and thirty-eight leaflets have already been issued dealing with topics as varied as "Liver Fluke Disease", "Results of Potato Variety Trials", "The Feeding of Bacon Pigs", "Turkey Production", "The Cultivation of Gooseberries" and the "Construction of Farm Dairying Buildings". The leaflets may be obtained free of charge from the Ministry of Agriculture, Stormont, Belfast.

The Plastics Institute

Sir Laurence Merriam, chairman of British Xylonite since 1959, has been elected president of the Plastics Institute for the session 1961–62. The following have been elected vice-presidents of the Institute for 1961–62: P. C. Chaumeton, Sir John Dean, P. A. Delafield, G. Dring, S. Ellice-Clark, G. W. Hodds, J. Lesser, W. F. Mitchell, A. E. Skan, Sir Miles Thomas, W. C. Waghorne, G. J. Wevell. The new ordinary members of Council for 1961–62 are: Dr. F. P. Hiron, M. Jones, M. Kaufman, A. A. Tomkins.

Fleming Memorial Fund

The Trustees of the Fleming Memorial Fund for Medical Research announce that the first grants from the Fund will be made before the end of 1961. The Fund exists to commemorate Sir Alexander Fleming, and his discovery of penicillin, by raising money to provide assistance for basic medical research anywhere in the world. This assistance may be given by grants to universities, research institutions and others engaged in basic medical research, and by way of national and international fellowships tenable at universities and research institutions. Applications should be sent to the Secretary to the Trustees, Fleming Memorial Fund for Medical Research, 26 Upper Brook Street, London, W.1, on or after October 1, 1961.

Announcements

Mr. F. Thistlethwaite, lecturer in the Department of Economics and Politics, University of Cambridge, has been appointed the first vice-chancellor of the University of East Anglia, Norwich.

Three meetings on "Nutrition in Latin America", organized by the Food and Agriculture Organization, will be held during the autumn: *September 27–October 7*, nutrition seminar for the Caribbean (Puerto Rico); *October 11–21*, seminar on nutrition education for Mexico and Central America (Guanajuato); *October 23–November 15*, joint symposium with the World Health Organization (Guatemala City). Further information can be obtained from the Food and Agriculture Organization, Viale delle Terme di Caracalla, Rome.

The eleventh annual instrument symposium and research equipment exhibition, sponsored by the Washington Sections of the American Association of Clinical Chemists, American Chemical Society, Instrument Society of America, Society of American Bacteriologists, Society of Applied Spectroscopy, Society for Experimental Biology and Medicine, will be held at the National Institutes of Health in Bethesda, Maryland, during October 9–13. Further information can be obtained from J. B. Davis, National Institutes of Health, Bethesda 14, Maryland.

The twenty-second national conference of the Council for the Preservation of Rural England is to be held at Southport during October 12–14. The subject of the conference, which is open to all, will be "The Impact of Industrial Development on the Countryside". Further information can be obtained from the general secretary, Sir Herbert Griffin, 4 Hobart Place, London, S.W.1.

The first European symposium on "Food Technology" is now to be held in Frankfurt (Main) during October 26–27, instead of October 19–20 as previously announced. Further information can be obtained from Prof. W. Diemair, Georg-Voigt-Strasse 16, Frankfurt (Main).

An international meeting on "Psychophysiology, Neuropharmacology and Biochemistry of Audiogenic Seizure" is to be held by the French National Centre for Scientific Research during November 6–9. Further information can be obtained from Prof. R. G. Busnel, Laboratoire de Physiologie Acoustique, C.N.R.Z., Jouy-en-Josas (Seine et Oise), France.

The International Atomic Energy Agency, the Food and Agriculture Organization and the World Health Organization are jointly organizing a conference on "The Use of Radioisotopes in Animal Biology and the Medical Sciences" in Mexico City during November 21–December 1. Further information can be obtained from the Joint Secretariat, Conference on the Use of Radioisotopes in Animal Biology and Medical Sciences, International Atomic Energy Agency, Kaerntnerring 11, Vienna.

List No. 29, "Forthcoming International Scientific and Technical Conferences", issued by the Department of Scientific and Industrial Research, amends and amplifies the information contained in List No. 28, which is superseded, from July 1961 to December 1962. As is the usual practice, conferences have been given chronologically and an index added to facilitate reference. The list is obtainable from the Department of Scientific and Industrial Research, Charles House, 5–11 Regent Street, London, S.W.1.

The fourth edition, revised to November 1960, of *A Bibliography of African Bibliographies, covering Territories South of the Sahara*, issued by the South African Public Library, Cape Town, includes some 1,450 entries, more than 350 of which are new, arranged according to the Universal Decimal Classification, with somewhat more intensive geographical sub-division (Grey Bibliographies, No. 7. Pp. iv + 79. (Cape Town: South African Public Library, 1961.) R. 2.00; 20*s*.). There is also an author–subject index combined.

SPACE-FLIGHT AND RE-ENTRY TRAJECTORIES

A SYMPOSIUM on "Space-Flight and Re-entry Trajectories", organized by the International Academy of Astronautics, was held at Louveciennes, near Paris, during June 19–21, 1961. The conference was opened by Prof. Theodore von Kármán, who has chosen to follow up his long and distinguished career in aeronautics by becoming the first director of the Academy. This symposium constituted the first meeting of the Academy, and the subject of trajectories was chosen, Prof. von Kármán said, because of its fundamental importance in the successful development of space flight. Though the Academy was now only beginning its activities, Prof. von Kármán was confident that in perhaps 100 years it would be as 'respectable' as the Academy of Sciences or the Royal Society. The present situation of astronautics reminded him of that of aeronautics when he first came to France in 1908. Then, aeronauts were regarded almost as madmen, and no one truly foresaw the later commercial and military applications of aircraft. Even the pioneer Lanchester was worried by the cost of upkeep of aerodromes, and thought they would have to be divided into two parts, to be grazed by cows in alternate years. With so many false aeronautical prophecies among his memories, Prof. von Kármán was confident of the future of astronautics.

The first scientific session, on "Trajectories for Lunar and Interplanetary Missions", began with a paper by J. M. J. Kooy (Breda, Netherlands) on "Astrodynamics and Planetary Research", which investigated the motion and uses of space-vehicles placed in orbit about a planet such as Venus. Then H. Hiller (Royal Aircraft Establishment, England) described the results of a generalized study of two-dimensional trajectories in the region of the Earth and Moon, and W. E. Moeckel (U.S. National Aeronautics and Space Administration) discussed interplanetary trajectories for electrically propelled space vehicles.

The second session, on "Orbital Transfer and Rendezvous", comprised three papers on the optimization of interplanetary trajectories, by D. F. Lawden (Canterbury, New Zealand), P. Contensou (Office National d'Etudes et de Recherches Aéronautiques, France) and B. Fraeijs de Veubeke (Liège, Belgium), and a general study of the techniques of orbital rendezvous by J. C. Houbolt (U.S. National Aeronautics and Space Administration). These subjects promise to expand greatly in the future, since both are essential to the economical performance of space missions and both pose severe mathematical problems.

In the third session, on "Near Earth Satellites", J. Kovalevsky (Bureau des Longitudes, Paris) made a general analytical review of orbital perturbations, D. G. King-Hele (Royal Aircraft Establishment, England) discussed the effect of atmospheric oblateness on satellite orbits, L. Sehnal (Ondrejov, Czechoslovakia) described luni-solar perturbations on a 24-hr. satellite, and K. Schütte (Munich) commented on the changes in the orbit of *Echo* 1.

The final session, on "Dynamics of Terminal Re-entry", was, ironically, delayed because the coach conveying the participants pursued a determinedly non-optimum terrestrial path from Paris to Louveciennes and took nearly 2 hr. to complete a journey nominally of 10 miles. In this session, A. Ferri and T. Ling (Brooklyn, U.S.A.) described the effect of varying lift on re-entry trajectories, W. F. Hilton (Hawker Siddeley, England) considered re-entry paths which avoid the zones of radiation, and errors in re-entry guidance were discussed by T. R. F. Nonweiler (Queen's University, Belfast) and L. Broglio (Rome). Finally, J. V. Becker, D. L. Baradell and E. B. Pritchard (U.S. National Aeronautics and Space Administration) investigated the methods of control for re-entry from escape speeds.

Although some of the papers seemed to be slightly out of touch with the present realities of space research, this was perhaps appropriate, or even inevitable, in a forward-looking academic symposium. Certainly the symposium as a whole can be counted a success, and the International Academy of Astronautics was wise to limit the numbers of those attending to about 80. Representatives from the U.S.S.R. were invited, but were unable to come. The papers presented at the symposium are to be published in *Astronautica Acta* later this year.

D. G. KING-HELE

BIOLOGY IN BRITAIN

By DR. H. V. WYATT

Department of Bacteriology, University of Leeds

SINCE the War, more and more exciting discoveries have been made in biology, but the classical biology of pre-war years has changed little. New techniques and brilliant men have opened new and fundamental subjects of inquiry, which cannot be wholly contained by the separated disciplines of botany and zoology but have found equal application in both subjects. Perhaps for the first time there is now a subject that can be called 'biology'.

A British biologist visiting the United States has at least two shocks in store for him; the first is the breadth of interest of his American colleagues and the second is the scope of the American undergraduate programme. In the United States there are departments in biology where the staff may include an ecologist, a physiologist, a biochemist, a microbial geneticist, a plant pathologist and perhaps an embryologist. An undergraduate may study zoology, botany, biochemistry, microbiology and genetics as well as chemistry. Afterwards, if he undertakes postgraduate studies, he will attend courses in an even greater variety of subjects. We may be doubtful and scoff 'superficial' and 'multiple-choice', and there are certainly faults in the American educational system, but the American biology graduate and Ph.D. is better equipped than the British counterpart, better equipped to teach other subjects, better equipped to read the journals, better equipped to do and to direct research. The advances that are being made are the results of the application of the techniques of one subject in others. Embryology is now studied by using techniques of biochemistry and immunology ; major advances have been made in genetics by the use of micro-organisms; micro-organisms have contributed to our understanding of biochemistry and now the biochemistry of deoxyribonucleic acid, the chemical basis of heredity, is being studied by using the viruses that infect bacteria. The artificial barriers are down: only the complete biologist can hope to map the new territories, although all the time the discovery of new landmarks makes it easier to find the way.

The emphasis in teaching is on the vertical division: animals and plants are catalogued in an ascending scale of morphological complexity corresponding to the natural evolution of the groups. But British practice in research is based increasingly on a horizontal structure; people who work on the active transport of inorganic ions and organic molecules use yeast, bacteria, plant roots, parasitic worms, mammalian red blood cells and so on. The fundamental properties of active transport are probably the same in all cells and can be studied in any convenient system; methods of studying it are peculiar to active transport and do not depend on the type of cell. From these studies we may discover whether cells of different origin behave in the same way or whether those differences we find have an evolutionary or an ecological significance. Already we have a pragmatic subject, microbiology, in which unity derives from common techniques and not from an evolutionary concept of a common ancestor. Research emphasizes the unity of modern biology; our teaching must do the same, for only by teaching biology as a unified discipline can we hope to train biologists adequately. It is essential that while we teach the latest findings of biochemistry and biophysics, we also give our students a love and understanding of living plants and animals. If the biologist is taught little biochemistry, the biochemist lacks contact with the living.

Many subjects are taught in isolation when their integration would make plain their coherent pattern. Recent experiments have shown that diet and behaviour may influence the interaction of parasite and host; behaviour is affected by the hormone balance of the animal, and this in turn is influenced by the animal's environment. We must frame our courses so that the student is made aware of such complex interactions. To do this we must persuade the staffs of our universities from the isolation of their departments. A degree of trade union demarcation has begun in our subjects; we now specialize so early that there is a tendency for the student with a first degree in microbiology, for example, to be restricted to that subject; although his techniques could be used there to advantage, he is rarely encouraged to apply for a job in a zoology department.

If the new biology is experimental and not in the first place descriptive, on what shall we model our course ? At least one course that we could copy is already in existence. For the Diploma of Technology in applied biology at the colleges of technology the emphasis after the first year is on physiology, biochemistry, pharmacology and microbiology. Elementary mathematics, statistics and organic and physical chemistry are also compulsory subjects. It is significant that these courses were planned by departments of biology in colleges where there had been no fragmentation into minor subjects. Although these courses have been planned with the view of the needs of industry, they are more suited for academic biology and research than are the courses offered at the universities. Sixth-form students may well think so too, as they read the topics and experience required in the "Situations Vacant" columns. Already our students may be learning more about modern biology from the *New Scientist*, the Penguin Science Survey and television than they gain from the isolated subjects studied at a university.

It is important that, in presenting the mosaic to show both the pattern and the basic units, we do not leave the student either bewildered or complacent. Bewildered if, faced with two thousand references about a single animal, he cannot imagine what more can be discovered or where to start; complacent, if he is presented with knowledge as a set of facts and theories and techniques as unquestionable. Both might be avoided by a detailed observation that would give competence with several techniques, an appreciation of the complexity of an organism and, most of all, an awareness that science is not dormant but militant. One evident way to attempt this would be to give a class several strains of a bacterium. Each week the class would study their own cultured strains in a progressive series of experiments. These could include growth, nutritional requirements, antibiotic sensitivity, genetics and phage-susceptibility—each of which contributes to the understanding of the others. If we base our undergraduate courses on modern experimental techniques with wide application, we can shed some of the crafts which now occupy so much time in school and university. As we do so, we may attract students who now take the physical sciences.

As soon as possible we must bring all the biological sciences together in one building. This is necessary not only so that the staff may feel that they are all biologists but in order that courses can be integrated. Staff using the same or similar techniques will be encouraged to collaborate and form new loyalties. Apparatus can be shared for both teaching and research. Physical and financial separation now makes this difficult. With the present departmental system, expensive apparatus is bought by one department, used, and afterwards lies idle. In another department, similar equipment is bought from another source. While we lack in the universities much modern equipment necessary for research, we continue to buy two pieces of apparatus where one would suffice.

A director of the National Science Foundation, which is revolutionizing the teaching of science in the United States, has written of the need for more experimental biology in Europe[1]. In Britain recently there has been argument for the creation of more chairs of biochemistry and molecular biology or biophysics. The need for such chairs is urgent: Prof. Irene Manton, in a recent broadcast, suggested that more chairs be created within existing departments; and, I may add, we need fusion of the biological sciences for teaching and research. Within a unified department of biology, it will be easier to add new disciplines than it is, nowadays, to create new departments.

RESEARCH WORK OF THE NATURE CONSERVANCY

An adjournment debate in the House of Commons on July 21, at which was discussed the research work of the Nature Conservancy, was opened by Mr. M. Kimball with an attack on the work of the Conservancy which showed a complete misunderstanding of the purposes and nature of the Conservancy. Nevertheless, the debate as a whole should prove a useful piece of publicity for the work of the Conservancy, which still lacks the resources necessary for an adequate publicity policy to remove misunderstandings such as those exemplified by Mr. Kimball's speech. On the matter of finance, it may be noted that, although several speakers commented on the inadequacy of the Conservancy's budget of no more than £500,000 a year, the Parliamentary Secretary for Science, Mr. D. Freeth, made no comment beyond saying that it is a matter for individual judgment whether the Conservancy's resources are too small.

Mr. Freeth, recalling the Director-General's description of the research programme as "a comprehensive attack on a range of ecological problems which are regarded as of fundamental significance for the advance of conservation", maintained that besides increasing scientific knowledge, the Conservancy's work is in the long run of great benefit to the nation. Of a staff of 250, 100 are scientists, and the Conservancy also maintains 40 postgraduate students working for doctorates in ecology and related subjects. It is, he insisted, a research council, and although it does its best to encourage interest in Nature and its conservation, this is not a primary purpose, and one has to recognize that many of the reserves are established to be sanctuaries for wild life, a purpose inconsistent with free access. The Conservancy welcomes at all its reserves scientists and university workers who have research to do which is likely to be of value. Mr. Freeth does not believe that there is overlapping with the work of other Government research organizations. There is considerable interlocking of personnel at a very high level, as well as on *ad hoc* committees, and the Select Committee on Estimates which explored the question of relations with the Forestry Commission in 1958 found no evidence to justify a recommendation to transfer to the Commission some of the fundamental research now undertaken by the Conservancy. Much of the Conservancy's research is basic in character and not suitable for dissemination through the National Agricultural Advisory Service.

The Conservancy, Mr. Freeth pointed out, controls about 8,000 acres of woodland, and research here is essential: first, to provide representative examples of the more important ecological types in their earlier stages of development; secondly, to provide adequate areas of managed woodland which would otherwise be threatened by systems of management more concerned with profit-making; and thirdly, to provide specialized facilities for undisturbed research and long-term field-trials. Mr. Freeth specifically denied the suggestion that the Nature Conservancy has ever established the breeding of coypu. For publicity or educational campaigns, or the issue and enforcement of regulations, the Conservancy has to look, for example, to the Ministry of Agriculture or of Transport.

As regards liaison and co-operation with county naturalist trusts and other bodies of naturalists, Mr. Freeth pointed out that the Select Committee on Estimates was impressed with the argument that unique opportunities for research would be lost if the Conservancy did not acquire as soon as possible the whole of the 250,000 acres envisaged. At present, 88 reserves represent 177,000 acres, and Mr. Freeth does not think it reasonable to delay proceedings merely because in a particular area a county organization has not been formed. He welcomed Mr. Kimball's praise of the Nature Conservation Corps, but to what was perhaps Mr. Kimball's most important point—that for only half the reserves has a five-year management plan been established—he made no reply. If this is due simply to financial stringency, it is time that the Minister for Science—and Parliament—acted.

SALMON AND FRESHWATER FISHING IN GREAT BRITAIN

Recently the Committee on Salmon and Freshwater Fisheries produced a stimulating report in which are made several recommendations which may lead to some very necessary changes in freshwater fishery legislation.*

Of major importance are the recommendations that the powers of the River Boards be extended. The report rightly appreciates that fishery problems are often localized and suggests that River Boards should be allowed to make by-laws to suit local conditions. Equally important are the recommendations that River Boards should have the power to demand accurate returns of catches from all licence holders. Clearly, adequate salmonid fishery conservation is greatly hampered by inaccurate returns of catches. As conservation to a large degree centres around re-stocking, it is obvious that the recommendation that no person be permitted to stock his waters without the consent of the River Board is pertinent: there is much more to stocking than the mere planting of fish.

Some valuable recommendations are made on the control by River Boards of the obstructions to migratory fish, and of particular importance in this context is the suggestion that a River Board should have the power to prevent any diversion of water unless sufficient water is passed down the original channel to avoid damage to fisheries. Equally sound is the point made that old dams, sluices, or leats in poor condition should be repaired by the owners, or alternatively demolished. Overcrowding in pools below unsurmountable weirs often results in dead fish during periods of high temperature and low water.

---

* Report of the Committee on Salmon and Freshwater Fisheries. (Cmnd. 1350.) Pp. viii+151+13 plates. (London: H.M.S.O., 1961.) 8*s*. net.

Pollution is dealt with admirably; and the suggestion that the Armer Committee's recommendations relating to the control of existing discharges should be extended to estuarine waters, should, if adopted, be highly beneficial to salmonid fisheries. I would like to see this control extended to all inshore waters.

The report stresses the need for more freshwater fishery research, and I am certain that the far too few freshwater-fishery biologists that are active in Britain will applaud the proposals that electric fishing and poisoning should be permitted for the purpose of scientific fishery research.

A report of this nature, which is of great interest not only to the 2½ million anglers but also to many industrialists, water undertakings and public bodies in Britain, will inevitably suffer much criticism. To a fishery biologist it suggests a beneficent revolution, but I find a few minor points of disagreement with the Committee. First, because only 2,000 netsmen are dependent, or partly dependent, on salmon fishing for their livelihood, because salmon anglers outnumber netsmen by about fifty to one and because anglers are of greater economic importance to River Boards, riparian owners, the tackle and tourist industry, I would recommend that netting be discontinued until salmon are much more plentiful. The netsmen should be adequately compensated. Secondly, I would recommend strongly that kelts should be preserved. As the report states, previously spawned fish form 5 per cent or more of salmon catches in the United Kingdom and thus represent at least 15 tons of fish; it would need several expensive hatcheries to produce this weight of fish. Thirdly, I would prohibit angling for salmon after the first week of September; in most cases this would protect the gravid fish and dispense to a large extent with the need for an accurate definition of unclean fish as discussed in the report. Fourthly, I would advocate a close season for coarse fish and that this be suited to local conditions. In addition, I would make it illegal for fishermen to return coarse fish above the minimum size, as many coarse fisheries are vastly overstocked and consequently the fishes are stunted. Lastly, I feel that the report should have stressed more strongly the need for research on coarse fish and I would suggest that this should be carried out in a national laboratory. I am certain that the River Boards and the River Boards Association would find such an institution invaluable.

Despite these objections the report is of major importance. It rightly emphasizes the remarkable achievements of the River Boards and its suggestions for the extension of their powers or for extended use of existing powers are expert, moderate and reasonable, as are its recommendations for compensation or non-compensation of affected interests. Everyone who has at heart the interests not only of the fisheries but also of rivers and lakes and the country as a whole will watch impending legislation closely and pray that the recommendations of the report become law with a minimum of mutilation and, above all, a minimum of delay. J. W. JONES

ELECTRIC CURRENTS ASSOCIATED WITH GEOMAGNETIC DISTURBANCES IN THE AURORAL ZONE

By DR. F. J. SCRASE

Meteorological Office, London

THE electric current systems in the high atmosphere in high latitudes, especially along the auroral zones, are complex and variable. The normal networks of geomagnetic observatories suffice only to provide inferences of the broader features of these systems. With the view of their more detailed study, the Special Committee of the International Geophysical Year, at its Rome meeting in 1954, recommended that some observatories in auroral regions should be supplemented by two subsidiary stations, in directions at right angles and about 20 km. from the main station, for the measurement of the horizontal space gradients of the magnetic elements.

In an article amplifying these recommendations, S. Chapman[1] explained how knowledge of a disturbance in horizontal magnetic force produced by a horizontal current flowing directly overhead, together with the vertical gradient of the disturbance, will indicate the strength and height of the current separately. Since the divergence and curl of the magnetic field are both zero, the vertical gradients can be derived from the horizontal gradients.

In accordance with the recommendation of the Comité Spécial de l'Année Geophysique Internationale, two subsidiary stations equipped with Askania variographs were set up near the Meteorological Office Geophysical Observatory at Lerwick (60° 08′ N., 01° 11′ W.) and were operated for part of the International Geophysical Year and its successor the International Geophysical Co-operation, 1957–59. One of the stations was at Aipleton, 26·7 km. south-south-west of the main station and the other at Bridge of Walls, 22·3 km. west-north-west. This article describes preliminary results of attempts to estimate the magnitude and position of the electric currents during some magnetically disturbed periods.

Method of Analysis

The disturbances selected for measurement were mostly those of the bay type of a few hours duration, but a few were sharp peaks of shorter duration. For each station the components of the disturbance vector were derived by measuring the maximum deviation with respect to an undisturbed part of the record shortly before the disturbance, or to the interpolated undisturbed value at the time of the maximum. It soon became evident that values of the horizontal space gradients derived from differences between records from the pairs of stations did not conform with the theoretical relationships between

Key to headings of columns: *Rn*, *Re*, *Rz* are distances north, east and vertically from Lerwick of the intersection of the current with the perpendicular from Lerwick; *C* is the current strength, positive sign indicating west to east; *A* is the horizontal direction of the current with respect to geomagnetic north; *I* is the vertical inclination of the current, positive directed downwards.

the field components associated with a horizontal line current. Thus, the gradients of the north components along the easterly direction were found not to be equal to the east component gradients in the northerly direction. There may be several reasons for this. For example, the differences over finite distances, about 25 km., may not be representative of the true gradients at a point; or the assumption of a simple line current may not be valid; or the effects of induced currents or of local anomalies may be significant. A similar difficulty with regard to the gradients has been reported by Cain[2] in a preliminary analysis of differential measurements made during the International Geophysical Year in Alaska.

However, it is not necessary to know the gradients in order to compute the magnitude and location of the current that produces the measured field disturbances at two or more stations. The line current should, in fact, coincide with the intersection of the planes through the stations normal to the directions of the total disturbance forces. The location and direction of such a current, relative to the stations, are thus obtainable, by co-ordinate geometry, from the measurements at any pair of stations. With three stations three sets of results are obtained, thus affording some check on the accuracy of the determinations. Knowing the perpendicular distance R of the line current from a station, the strength C of the current is obtained from $C = f.R/2$, where f is the total disturbance force at the station. To avoid introducing a questionable factor, the effect of induced currents has not been taken into account in these computations, but the magnitude of the effect is considered later.

For the preliminary investigation, 22 records of disturbances were selected for measurement; these showed station differences in one component or another sufficiently marked to lead to reasonably consistent estimates of the currents. The disturbances (in total force) ranged from about 100 to 400γ, with station differences of a few tens of gamma. In some cases measurements from only one pair of stations were available.

The main results are presented in Table 1, in which the occasions are arranged in the order of the time of day at which the disturbance (maximum) occurred. No attempt was made to select disturbances according to the time of day, however, and their distribution may be taken to indicate that measurable disturbances occurred more rarely between 04 hr. and 14 hr.; this conforms with the almost complete absence of radar echoes from aurora in the morning daylight hours 06–12 hr. The fact that the results are confined to the period between April and October, however, does not indicate that disturbances rarely occurred in winter.

The computed locations of the currents relative to the positions of the stations are plotted in Fig. 1. In each case the relative magnitude and the azimuth of the current are indicated by the length and direction of the line, the mid-point of which represents the intersection with the perpendicular (3-dimensional) from Lerwick. It will be seen that most of the currents are located to the north-north-west of Lerwick between geomagnetic latitudes 62·5° and 63·5° N. Observations at the Balfour Stewart Auroral Laboratory from the area from the Western Atlantic to Central Europe indicated that auroral displays were reported on most of the days of the magnetic disturbances and that the bases of the auroral arcs were overhead in lat. 62°–67° and rays overhead in lat. 59°–64°.

Fig. 2 shows how the main features of the currents vary with the time of day. The most marked change is in the direction of the currents, which is from west to east between 15 hr. and 20 hr., and east to west from 22 hr. to 03 hr. This is in agreement with deductions made by Goldie[3] from magnetic storm disturbance vectors and also with the visual, photographic and radar echo observations of auroral move-

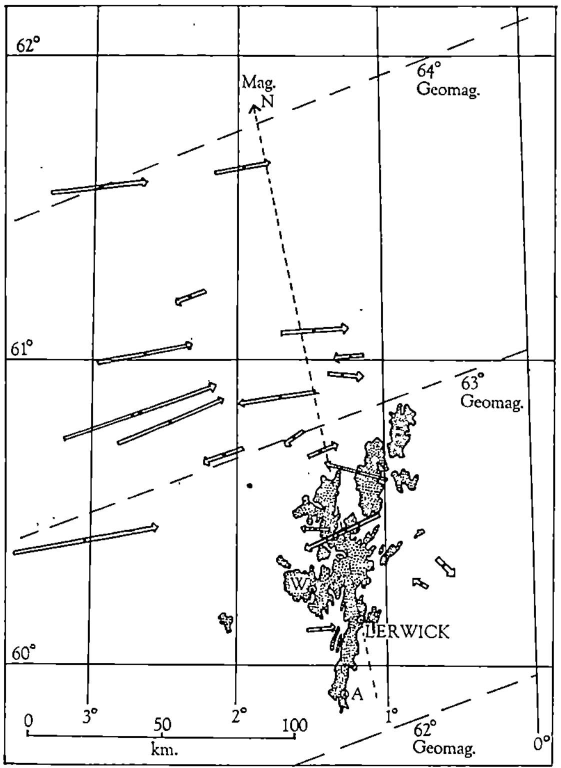

Fig. 1. Location of auroral zone currents

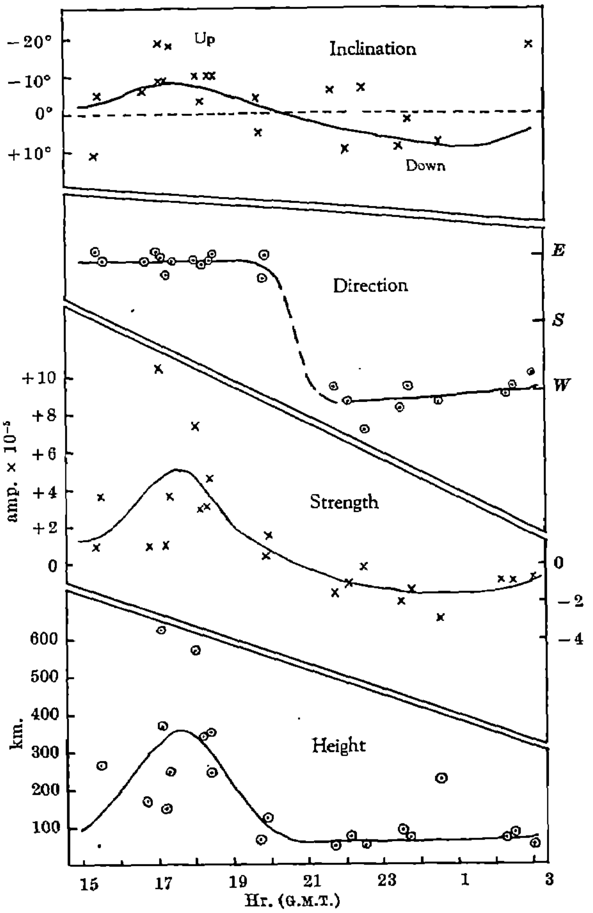

Fig. 2. Auroral zone currents derived from magnetic records

ments reported by various observers. The mean directions of the currents are more nearly parallel to the direction along local geomagnetic east and west than to the lines of geomagnetic latitude, the differences being about 5° and 15° respectively. This result is in conformity with observations of auroral rays (McInnes and Robertson[4]) and with recent auroral radio echo measurements (Watkins[5]).

The current strengths reach a maximum, of about 10^6 amp. in the west to east direction, between 17 hr. and 18 hr., fall to zero at about 21 hr. and then increase to a smaller maximum of about 3×10^5 amp. at about 0 hr. These current strengths are of the same order of magnitude as those determined by Goldie[3] for large magnetic storms.

The calculated values of the inclination of the currents to the horizontal (at Lerwick) show considerable scatter, but there does appear to be a tendency for the west–east currents to be inclined upwards and the east–west downwards by about 5°. This departure from the horizontal is too large to be accounted for by the Earth's curvature; at the extreme distance west of Lerwick of the currents shown in Fig. 1, the curvature should not cause an apparent departure of more than about 2°.

Probably the most interesting feature shown in Fig. 2 is the variation in the height of the currents. As in the case of the strengths, there is a maximum at about 17.30 hr. Between 15 hr. and 19 hr., most of the currents were at heights between 150 km. and 350 km., that is, at about the levels of the $F1$ and $F2$ layers of the ionosphere, but two appeared to be near 600 km. After 20 hr. and until 3 hr., the heights of the currents were centred at about 80 km., that is, near the E layer of the ionosphere and at about the average lower limit of auroral visual forms and of maximum auroral light. Most of the radio observations of aurora indicate that echoes originate from that layer, but radar reflexions have been detected from levels as high as 300 km. and observations of the scintillation of radio stars have indicated disturbances in ionization at these levels. From Goldie's determinations from magnetic storms of outstanding magnitude, heights of currents of between 230 km. and 390 km. at all hours of the day were deduced, but in storms of a more ordinary category the heights fell to about 100 km. between 0 hr. and 4 hr.

Effect of Induced Currents

It has already been mentioned that, in deriving the results described here, no account has been taken of the possible effects of induced currents in the Earth. That they are not negligible is shown by comparing the elevations of the vectors of disturbances recorded simultaneously at Lerwick and at Eskdalemuir about 500 km. south of Lerwick. Although the total disturbance forces recorded at Eskdalemuir are roughly of the magnitude expected at the distances from the currents computed from the Lerwick network observations, the elevations of the forces are all much greater than expected. This is also evident in the Eskdalemuir and Lerwick data used by Goldie[3] already mentioned; but fortunately he realized that the elevations at Eskdalemuir were more liable to be in error and used the total forces in his computations. The discrepancies in the elevations can, however, be largely accounted for if we assume the existence of an induced current, equal and opposite to the overhead current, at a depth of the order of 800 km. below the Earth's surface. Estimates of the depth in individual cases varied between 550 km. and 1,100 km. It is known that the electrical conductivity of the Earth, which is very small down to a depth of 600 km., where it has a value of 10^{-3} ohm.$^{-1}$ cm.$^{-1}$, rises rapidly to reach a value of at least 10^{-2} ohm^{-1} cm.$^{-1}$ at a depth of 900 km. (Lahiri and Price[6]).

In the method adopted for computing the overhead currents, the nearer the observing station to the seat of the currents the smaller are the errors caused by neglecting the induction current. If the effect of the latter at the depth of 800 km. is allowed for in the computations for the Lerwick network, the calculated heights and strengths of the overhead currents would be reduced by roughly 30 per cent, but the general trend of the daily variation shown in Fig. 2 would not be changed significantly.

Density of Ionization

If, as is now generally accepted, the currents of the auroral zone result from the movement of the ionization that is responsible for the aurora, it should be possible to relate the current strength C with the velocity of auroral motion V. At about 18 hr., when the currents reach their maximum value of about 10^6 amp. in the easterly direction, auroral speeds are of the order of 1 km. sec.$^{-1}$ in the westerly direction (Ratcliffe[7]). If, then, these currents are produced by the westerly drift of negative ionization at this speed and if the area of cross-section of the stream of ionization is A, then the electron density can be estimated from $n = C/e.V.A$, where e is the electronic charge ($1\cdot6 \times 10^{-19}$ coulomb). Recent radar echo observations of aurora (Eastwood[8]) suggest that the region of ionization in which the reflexions take place is about 20 km. thick, and so an appropriate value of A would be 400 km.^{2}. These figures lead to an estimate of the electron density of:

$$n = 10^6/(1\cdot6 \times 10^{-19} \times 10^5 \times 400 \times 10^{10}) = 1\cdot5 \times 10^7 \text{ cm.}^{-3}$$

This is a reasonable value for disturbed conditions in the ionosphere.

This communication is published with the permission of the Director-General of the Meteorological Office. It is hoped to publish a more detailed account of the work in due course.

GRAVITY SURVEY ON THE AIRA CALDERA, KYUSYU, JAPAN

By IZUMI YOKOYAMA

Geophysical Institute, Hokkaido University, Sapporo

THE Aira caldera, in the southern part of Kyusyu, Japan, is one of the biggest in the world, measuring about 20 km. in diameter. It occupies the innermost part of Kagosima Bay, and an active volcano, Sakurazima (1,118 m. high), stands on its southern circumference. This volcano came into existence after the formation of the Aira caldera. The bottom of the caldera is the rather shallow (about 150 m. deep) and flat floor of Kagosima Bay and the steep cliffs occurring at several sea-shores have been supposed to be parts of the encircling caldera rim. A tremendous volume of volcanic ejecta, ignimbrite and pumice flows, which covers a wide area around Kagosima Bay, has been proved to have been ejected when the caldera was formed.

As reported before, my colleague and I[1] found a conspicuously low Bouguer anomaly on the Kuttyaro caldera lake in Hokkaido, which amounts to a maximum of 46 mgal. extending over 20 km. Since I considered such a low gravity anomaly as one of the characteristics common to the calderas of so-called Krakatoa type, the formation of which was accompanied by the ejection of vast quantities of matter, I tried to verify the similar gravity distribution on the Aira caldera. A gravity survey by means of a North-American gravimeter was carried out there in August 1960 in co-operation with the Geographical Survey Institute. Almost all the observation points are the bench-marks for precise levels. The Bouguer anomalies observed around the caldera and along the coast-line of the Sakurazima Peninsula are shown in Fig. 1, where topographical corrections are smaller than 1 mgal. for all observation points and can safely be ignored. As shown in Fig. 1, a relatively low anomaly is very conspicuous around the Aira caldera, the lines of equal anomaly being exactly concentric with the supposed caldera rim. At the northern boundary where there is no characteristic topography of the caldera rim, it is not easy to discriminate exactly only the effect of the Aira caldera on the gravity field, in other words, some residual anomalies due to the caldera, but one may easily extrapolate the tendency of decrease in the Bouguer anomaly observed on land to the centre of the caldera, though no observation in the Bay is available. At the north of Sakurazima, perhaps the minimum value of the Bouguer anomaly may reach about − 25 mgal. and hence the relative anomaly to the surroundings may amount to about − 45 mgal. Further, the centre of this anomaly coincides with one of the topographical depressions at the time of the great 1914 eruption of Sakurazima. Along the coast of Sakurazima itself, the anomalies are negative at the northern side and positive at the southern side, while the axis of inversion of the sign is almost the same as that of the crustal tilt which accompanied the recent activities of the volcano. The active volcano Sakurazima has scarcely any effects on the general distribution of the Bouguer anomaly on the caldera: this means that the size of the structure of a recent volcano cannot be compared with that of a gigantic caldera so far as density contrast is concerned. The anomaly suggested by the present survey, about

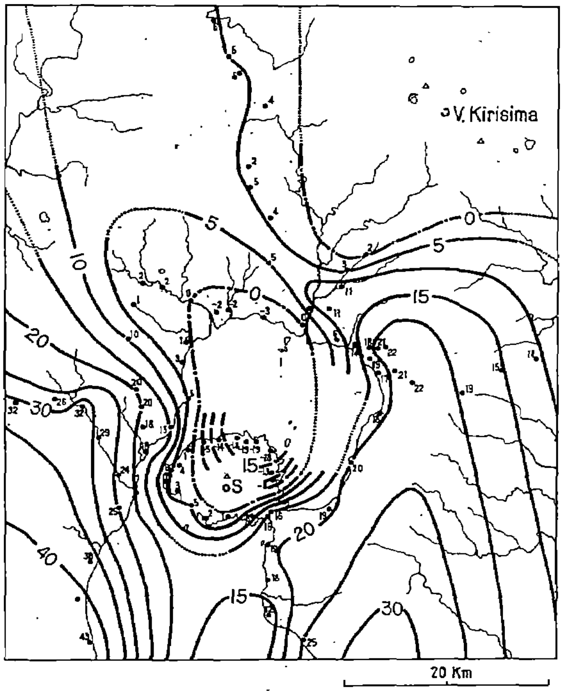

Fig. 1. Distribution of the Bouguer anomalies on the Aira caldera. Unit is the mgal. *S*, crater of Volcano Sakurazima

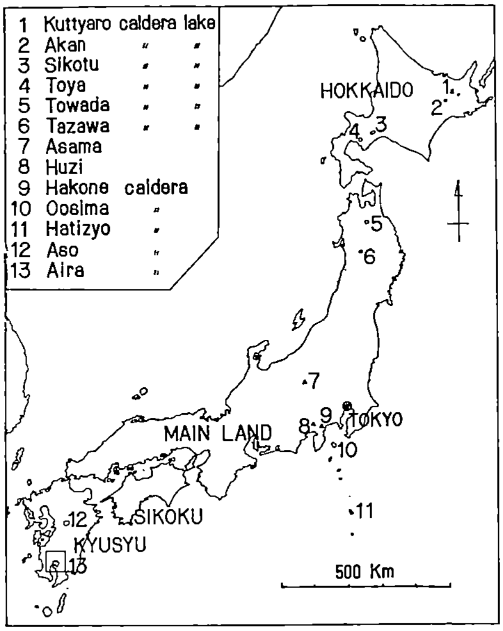

Fig. 2. Calderas in Japan

45 mgal. at its maximum extending over 20 km. in diameter, is very conspicuous and incidentally of just the same magnitude as the Kuttyaro caldera. Therefore, it is concluded that coarse material with a density about 0·3–0·5 gm./cm.^{3} smaller than that of its surroundings has accumulated at a depth of 3–4 km. beneath the caldera. The distribution of the Bouguer anomalies gives the total mass defect, which is responsible for the low anomalies, as 1·6 × 10^{11} metric tons. In fact, the material ejected from the caldera during its formation was deposited as ignimbrite and pumice flows around the caldera; its amount is estimated at 1·6 × 10^{11} m.^{3} by B. Koto[2].

Table 1

Caldera	Diam. (km.)	Age	Deposit	Bouguer anomaly (mgal.)	Observer
Kuttyaro	20–26	Pleistocene	Ignimbrite	−46	Refs. 1, 3
Akan	13–24	Pleistocene	Ignimbrite	−25	Ref. 3
Oosima	3–4·5	Holocene	Subsidence of basaltic lavas	+15	Ref. 4
Aso	17–25	Pliocene	Ignimbrite	−20	Ref. 5
Aira	23–24	Pleistocene	Ignimbrite and pumice flows	−45	
Volcano	**Height (m.)**	**Age**	**Rock**	**Bouguer anomaly**	**Observer**
Asama	2,542	Holocene	Andesite	Normal	Ref. 6
Huzi (Fuji)	3,776	Holocene	Basalt and andesite	Normal	Ref. 7

In Japan there are some ten calderas as shown in Fig. 2, some of which have been studied gravimetrically. The results of the observations on the calderas and volcanoes are summarized in Table 1.

From these data, though examples are not abundant, it can be seen that the Bouguer anomalies on the calderas can be classified in two types: (1) low anomaly, that is, Kuttyaro type; (2) high anomaly, that is, Oosima type. It can further be seen that they are almost normal on the large stratified volcanoes without caldera, such as Huzi (Fuji) and Asama, after consideration of topographical corrections. The two types of Bouguer anomalies correspond geologically to two types of calderas, the Krakatoa and the Glencoe types of H. Williams[8], according to the cause of their formations as discussed in ref. 1.

On the other hand, L. C. Pakiser, *et al.*[9] carried out a geophysical investigation in the Mono Basin, California, which is a volcano-tectonic depression surrounded by a large amount of pumice; they found a residual gravity relief of about − 50 mgal. extending over 25 km. It is very noticeable that the magnitude of this anomaly is of the same order as the Japanese large calderas. E. Medi and C. Morelli[10] made a gravity survey in Sicily and found no anomaly on Etna (3,274 m. high) as was also the case on Huzi and Asama. In effect, the contrasts of the Bouguer anomaly between large calderas and stratified volcanoes are very remarkable with respect to subterranean structure or depth of origin, shallow for the former and deep for the latter.

I wish to thank the authorities of the Geographical Survey Institute for their kind co-operation in this work.

ETHYLENE EVOLUTION AND SUB-CELLULAR PARTICLES

By Prof. STANLEY P. BURG and ELLEN A. BURG

Department of Physiology, University of Miami School of Medicine, Florida

DURING the past ten years there have been at least five separate reports of the preparation of cell-free systems capable of evolving ethylene. The earlier claims relating to soluble systems, acetone powders and breis[1–3] have been criticized on many counts and in particular the specificity of several of the assay methods is questionable[4]. In fact, it is doubtful whether certain of the plant sources which were used actually produce measurable quantities of ethylene, for example, etiolated peas and oats[2]. More recently, the report by Spencer[5] of the preparation of a particulate ethylene-producing system from tomatoes has been disputed by Meigh *et al.*[6], who were unable to confirm the results using either tomatoes or apples. We also have had no success in preparing a sub-cellular system which evolves ethylene, using apples, tomatoes and the fungus *Penicillium digitatum* as sources of enzyme and the techniques of Hall[1,2], Dimond and Waggoner[3], Spencer[5] and other conventional procedures. The most recent report of ethylene production by a particulate preparation is that of Lieberman and Craft[7], who used an acidic medium to isolate active fractions from both tomatoes and apples. It is the purpose of the present article to indicate that the volatile substance emanating from these particles is not ethylene, and hence that ethylene production by a sub-cellular system remains to be demonstrated unequivocally.

A single tomato in an early pink stage was homogenized at 4° C. with an equal volume of *p*H 6 buffer (0·05 *M* phosphate, 0·5 *M* sucrose), using a Waring blender for 1 min. at slow speed. The homogenate was passed through four layers of cheesecloth, after which 500*g* (15 min.) and 17,000*g* (30 min.) fractions were obtained by differential centrifugation. Each fraction was washed by re-sedimentation and the pellets were suspended in 5 ml. of *p*H 6·2 sucrose–phosphate buffer. Into a 5-ml. syringe were drawn successively 1 ml. of particles, the co-factors (listed below) contained in 0·6 ml. buffer, and 3 c.c. of air. The needles were sealed by insertion into rubber stoppers, syringes were incubated at 30° C., and finally the entire gaseous contents were analysed by pressing out all the fluid and gas chromatographing the remaining air on an aluminium oxide column. A flame ionization detector similar in type and sensitivity to that used in refs. 6 and 7 was used, so that the major difference between the present experimental technique and that described in their original communication in *Nature* is the substitution of an aluminium oxide adsorption column for the silicone oil partition column. However, it should be noted that details of the procedure by which 'acidic' particles[7] were prepared from tomatoes and apples have not yet been published, so that it is impossible to state with absolute surety that our sub-cellular preparation is comparable in all respects.

It was found that a gas similar to ethylene was evolved by both washed and unwashed 500*g* and 17,000*g* particles when adenosine triphosphate, coenzyme A, magnesium chloride, phosphate and thiomalic acid were included in the incubation mixture (see Table 1: 'ethylene-like' substance). The rates per ml. are closely comparable with those reported by Lieberman and Craft, although an exact comparison is not possible since the nitrogen content of our preparation was not determined. As shown in Table 1, the particles behaved in every respect in the manner which has previously been reported[7]: a requirement for thiomalate and thioglycolate is only very slightly replaced by cysteine and glutathione, the reaction is essentially inhibited by boiling the enzyme preparation, the evolution is strongly inhibited by 10^{-3} *M* ethylenediaminetetraacetic acid (EDTA), and both 500*g* and 17,000*g* fractions are active. In addition, the rate in the presence of thiomalic acid was found to be linear for almost 60 min. at 30° C. However, the gas which the particles produce does not co-chromatograph with added ethylene, as shown in Fig. 1, its peak being distinctly separated from that of authentic ethylene. Moreover, as shown by gas chromatography, neither bromine water nor mercuric perchlorate solution removed the substance from air, whereas these reagents were found consistently to eliminate comparable quantities of ethylene from synthetic air–ethylene mixtures. Thus it is established that the gas produced by these particles definitely is not ethylene. Since the substance is observed to chromatograph between ethane and ethylene, it may be a two-carbon compound, and it is most likely organic as it produces a response with the flame ionization detector.

Table 1. Production of an 'Ethylene-like' Substance by Cytoplasmic Particles from Tomatoes in the Presence of Thiomalic and Thioglycolic Acids

Syringe contents*	μl./c.c. particles/hr.	
	'Ethylene-like' substance†	Ethylene
Particles + co-factors	0·0013	0·0003
Particles + co-factors + thiomalate	0·0343	0·0006
Particles + co-factors + thioglycolate	0·0314	0·0005
Particles + co-factors + glutathione	0·0038	0·0002
Particles + co-factors + cysteine	0·0041	0·0004
Boiled particles + co-factors + thiomalate	0·0023	0·0007
Particles + co-factors + thiomalate + EDTA	0·0035	0·0005

* The syringe contents consisted of the following: 50 μ*M* thiomalate, glutathione, cysteine or thioglycolate; 3 μ*M* adenosine triphosphate, 60 μ*M* phosphate; 0·08 μ*M* coenzyme A, 400 μ*M* sucrose, 25 μ*M* $MgCl_2$, 1·6 μ*M* EDTA. The *p*H of the reaction mixture was 6·2 and the syringes contained 1·6 ml. of liquid and 3 c.c. of air. The syringes were incubated at 30° C. for 60 min.

† These values are derived on the basis of a calibration of the flame detector for ethylene, but since the sensitivity of the instrument depends on the number of carbon atoms in the compound, the rates will be in error if the 'ethylene-like' substance does not possess two carbon atoms in its structure.

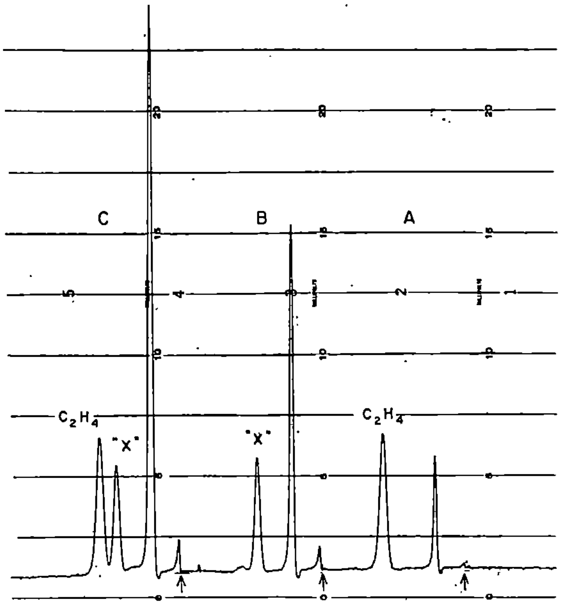

Fig. 1. Gas chromatogram of (*A*) an authentic sample of ethylene, (*B*) volatiles produced by tomato particles, and (*C*) a co-chromatograph of *A* and *B*. The graph reads from right to left and one vertical division corresponds to 30 sec. Samples were inserted at the times indicated with arrows. A 24-in. activated alumina column (Burrell) was operated at 23° C. with a nitrogen carrier gas flow-rate of 10 c.c./min. and a hydrogen flow-rate of 15 c.c./min. The first peak in each case represents a mixture of all unretarded components of the sample, and the 'ethylene-like' substance is labelled '*X*' on the graph

A close examination of Fig. 1*B* reveals that there is a minute trace of a volatile material, amounting to a few per cent of the major unknown component, which has the same retention time as authentic ethylene. Its identity as ethylene was confirmed by the observation that treating the sample with either bromine water or mercuric perchlorate reagent caused it to be absent from a subsequent chromatograph. It is important to note that the production of ethylene, within the limits of accuracy which can be obtained with such small quantities of material, is shown in Table 1 to be independent of the co-factors and substrates included, and the boiled preparation is at least as active as any other. Within a 25-min. incubation time, which was the briefest collection period investigated, the formation of ethylene had ceased in all cases. Therefore, the trace of ethylene is perhaps not due to a metabolic reaction, but rather to a contamination of unknown origin which is present, or formed by chemical reaction, at the start of the incubation.

Undoubtedly one of the stimuli which has prompted the search for a particulate preparation able to evolve ethylene is the observation that intact tissue responds to treatment with solutions of varying tonicity as though the ethylene-producing system were located in a particle having a semi-permeable membrane[8,9]. This evidence is indirect, and the interpretation can only be validated by the actual demonstration of ethylene evolution by a particulate fraction. However, the behaviour of mitochondria, which may display no endogenous uptake of oxygen although able to consume oxygen on the addition of appropriate substrates, makes it unlikely that particles will be shown to evolve ethylene unless a specific substrate is added. This situation is made even more difficult by the complication that cutting tissue into very small pieces seems to hinder ethylene production markedly[6,10].

In all properties investigated, the particles described in this article appear to be similar to the sub-cellular fractions prepared by Lieberman and Craft provided that our 'ethylene-like' substance is equated with their ethylene. If this is valid, then it must be concluded that none of the claims of ethylene production by cell-free systems can be supported, and that of Lieberman and Craft is no exception. It will be necessary to know more about the substrate from which ethylene is derived before such experiments are likely to be successful.

A grant (*RG* 8124) from the National Institutes of Health provided support for this investigation. We thank Prof. K. V. Thimann for his criticism and advice.

OXYGEN ELECTRODE FOR MEASUREMENT OF TISSUE SLICE RESPIRATION

By E. H. STRICKLAND*, F. D. ZIEGLER and PROF. A. ANTHONY

Biophysics Laboratories, Pennsylvania State University, University Park, Pennsylvania

SUBSTANTIAL progress has been made in using polarographic methods to measure oxygen concentrations in a number of biological systems, such as blood[1], mitochondria[2] and bacteria[3]. Improved reproducibility and simplicity of operation have been achieved by refinements in the oxygen electrode, for example, the Clark electrode[4]. The present article describes a continuously recording tissue slice respirometer which uses a Clark oxygen electrode covered with a ½ mil 'Teflon' membrane. This system allows convenient measurement of rapid changes in respiratory-rates.

The tissue slice respirometer constructed in this laboratory is shown in Fig. 1. The reaction medium is kept uniformly mixed by magnetic stirring, so that addition of reagents does not alter the steady-state diffusion conditions for more than a few seconds. A sealed electrode vessel prevents oxygen transfer from the atmosphere. Thus, any oxygen consumed by the slice must come from the medium.

The uses of the tissue slice respirometer can be illustrated best by outlining the detailed procedure followed in a typical experiment. The results obtained in one such experiment are shown in Fig. 2. The first step was to fill the vessel with reaction medium and turn on the magnetic stirrer. The current-level corresponding to an air-saturated reaction medium (240 μM) was then measured. Next, the magnetic stirrer was turned off to reduce bubble formation to a minimum when introducing a slice of tissue. This accounts for the large decrease in electrode current evident in Fig. 2. A slice of heart ventricle from a rat was added to the vessel, which was then sealed with a vaccine bottle stopper containing an outlet syringe needle. About ½ ml. of reaction medium was injected into the vessel to force any trapped air bubbles through the outlet syringe. Finally, the stirrer was turned on again, causing the electrode current to increase rapidly. When the new diffusion conditions reached a steady state (about 20 sec.), the electrode recorded the endogenous respiration (0·25 μmole oxygen/sec.), which is the slope of the curve at this

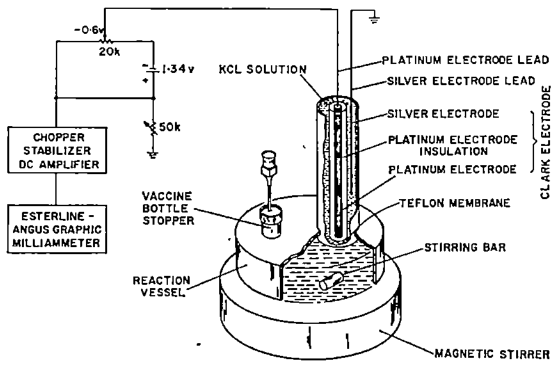

Fig. 1. Oxygen electrode system used for measurement of tissue slice respiration. The reaction medium is stirred rapidly enough so that the electrode current is independent of the rate of stirring. The electrode current is linearly dependent on the oxygen concentration (± 7 per cent) as determined by the measurement of the respiration of baker's yeast

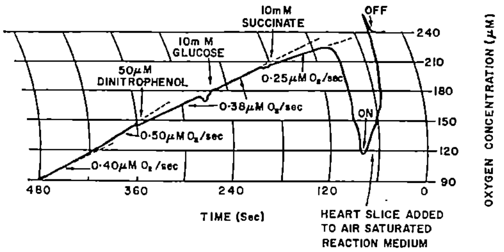

Fig. 2. Record of respiration of a slice of heart ventricle in several different respiratory states. Reaction medium containing 90 m*M* sodium chloride, 5 m*M* potassium chloride, 1 m*M* magnesium chloride and 40 m*M* phosphate buffer, *p*H 7·3. Temperature, 24° C. On–off refers to the magnetic stirrer

point. Injection of succinate into the vessel caused respiration to be stimulated by 50 per cent (to 0·38 μmole oxygen/sec.). Subsequent addition of glucose failed to stimulate respiration further. Following that, an injection of 2,4-dinitrophenol produced an additional 30 per cent increase in oxygen consumption (to 0·50 μmole oxygen/sec.).

This experiment illustrates how the oxygen electrode can be used to investigate the respiration of the same tissue slice in several different metabolic states. For example, the stimulation of respiration by dinitrophenol indicates that a low concentration of adenosine diphosphate in the tissue is limiting the rate of respiration in the presence of succinate. This agrees with recent findings of other workers, who used different methods for investigating muscle respiration[5,6]. The failure of glucose to stimulate respiration in the presence of succinate suggests that the penetration of glucose into the tissue slice is not rapid. If the glycose had penetrated into the slice, it would have been rapidly phosphorylated, thereby increasing the concentration of adenosine diphosphate. Any internally generated adenosine diphosphate would have stimulated respiration. No such respiratory stimulation was observed with the addition of glucose in the present experiment.

At the lower left corner of Fig. 2 the respiratory rate began to decline. This decreased respiration occurs at low oxygen pressures due to a decreased intracellular oxygen concentration. In practice, measurements are not made at such low oxygen pressures. By using an oxygen-saturated medium instead of an air-saturated medium, the respiratory rate of tissue slices is independent of the oxygen pressure over a much wider range of pressures.

It should be apparent from this that the oxygen electrode respirometer has many advantages over the manometric technique for work on tissue slices. The polarographic technique is especially useful for investigating the factors regulating respiration in tissue slices. Studies similar to that shown in Fig. 2 should facilitate greatly investigation of the action of chemical agents, such as drugs or hormones, on respiration. A relatively simple experiment can be used to determine whether such agents have any effect on the endogenous level of adenosine diphosphate, the substrate concentration, or the respiratory enzymes. Such information can be obtained by measuring respiratory rates in different metabolic states[6,7]. To obtain such information by manometric techniques would be much more time-consuming and less accurate. One can conclude from our work that a wider future application of the oxygen electrode for measurements of tissue slice respiration should prove extremely fruitful.

This investigation was aided in part by grant *RG*-5112 (*R*2), U.S. National Institutes of Health.

PERSISTENCE IN ERYTHROCYTE GHOSTS OF MEDIATED SUGAR TRANSPORT

By PAUL G. LEFEVRE*

Medical Research Center, Brookhaven National Laboratory, Upton, New York

THE special mechanism by which the common monosaccharides traverse the surface of the mammalian red blood cell has been the subject of considerable investigation in recent years[1–6]. Diverse experimental procedures, concerned primarily with analysis of the kinetics of sugar movements both into and out of the cells, have led to the conclusions that: (*a*) the permeation of the sugars through the cell surface occurs by way of a transient stoichiometric association with a limited number of reactive sites which are accessible at the cell surface to the two aqueous compartments (inside and outside the cell); (*b*) the translocation of the associated sugar-complex between the inner and outer interfaces of the surface layer results either from simple diffusion or from some kinetically indistinguishable process requiring no investment of metabolic energy. This mechanism, generally prominent in fœtal erythrocytes[2], does not persist at a comparable level of activity in the adult except in the human and certain other primate species. Typically, such cells are virtually impermeable to structurally related polyhydric alcohols, and even to certain sugars, which, though isomeric to the transported kinds, are of unsuitable steric arrangement[4]. Moreover, application of a variety of blocking agents[1] may completely stop the penetration of the transported sugars without radically altering permeability to small unrelated solutes.

Thus the specific reactive sites are generally held to be located at the semi-permeable barrier classically identified with the plasma membrane, which would apparently restrain all monosaccharides from entering the cell, were it not for this special mechanism. This raises the question whether the red cell ghost, retaining many of the surface characteristics of the original cell would also display the specialized sugartranslocating behaviour which the barrier shows in the intact cell. It is known from Teorell's observations that ghosts may continue to take in glucose while still excluding sucrose[7]; but Teorell did not examine whether this could be attributed to a free diffusion or to a surviving mediated-transfer activity. This question was therefore specifically examined by quantitative comparison of red-cell suspensions and derived ghost suspensions in respect to D-glucose movements. These experiments indicate that the membrane transport continues to function at full capacity after removal of the bulk of the original intracellular material. Thus, densitometric records of ghost volume changes with time (Ørskov's method[8]) continue to follow satisfactorily the predicted relation:

---

* Present address: Department of Pharmacology, School of Medicine, University of Louisville, Louisville 2, Kentucky.

$$kKt = (C_s + 1)(C_s + K)(C_s + K + 1)(V_0 - V) + (C_s + 1)(C_s + K)^2 \ln \frac{1 - V_0}{1 - V} \quad (1)$$

where k is a maximal flux constant, compounded from the diffusivity of the complex in the membrane and the fixed density of reactive sites; K is the dissociation constant of the complex and C_s is the external sugar concentration, both expressed in physiologically isosmotic units (isotones); and V_0 is the value at zero time of V, the intracellular (intraghost) water volume expressed as a fraction or multiple of its value at isotonicity. (This relation derives directly from integration of equation (1*b*) of ref. 6, for the case where the sugarless medium is isotonic and much larger in volume than the cells, as in Ørskov's procedure; though differently expressed, it is identical with equation (12) of ref. 3.)

Human blood was collected into standard ethylenediaminetetraacetic acid platelet packs ('Fenwal') from polycythæmic patients undergoing therapeutic phlebotomy, and stored at 2–4° C. when not used the same day. (In several years of related work on both normal and polycythæmic bloods, no indication has appeared of any relevance of this disease state to the sugar-transfer system.) Just prior to preparation of the ghosts, cells separated by centrifugation were taken through at least three successive washes in relatively large volumes of normal saline (Baxter) and finally two or three washings in a buffered balanced-salt medium[6]; in the course of this procedure, the major part of the white cells was discarded along with the uppermost red cell layers. Cells packed to about 75 vol. per cent in this medium were lysed by abrupt addition of (usually) 4 or 5 volumes of distilled water, and the hæmolysis reversed after 10–60 min. by addition of hypertonic sodium chloride, potassium chloride, or balanced salt mixture, sufficient to restore or slightly exceed isotonicity; finally, the ghosts were reconstituted by centrifugal washings in the isotonic medium and stabilized therein by 30–60 min. incubation at 37° C. before beginning experimentation. Cell and ghost volumes, counts and hæmoglobin contents were estimated by standard methods[6]; water contents by wet and dry weighings and sodium and potassium contents by flame photometry, through the courtesy of Dr. L. K. Dahl.

The ghosts prepared as described above were comparable with Ponder's preparations in retaining, typically, about a quarter of the original cell hæmoglobin and slightly less than half the original cell volume. In Ørskov's apparatus, they showed approximately the same transmission as intact cells at the same volume concentrations (that is, ghosts at about twice the cell count); this contrasts with the experience of Stein[10], who reported a marked increase in transmission at a given suspension concentration, with ghosts even less depleted than these. Densitometric comparison of these ghosts with intact cells in regard to glucose entry or exit at 37° C. showed essentially identical resistances to permeation: in response to a given applied sugar gradient, the ghost equilibration-rate was about double that of the cells, in appropriate proportion to the depletion of the original cell water and total solute. Compliance with this relation was further tested by varying widely the relative volumes of water used for lysis of several aliquots of ghosts, providing, after reconstitution, a series of ghosts of differing average volume. As shown in Table 1, the acceleration of equilibration progressed in pace with the depletion of the water space, implying an essentially unchanged membrane-transfer capacity even in the most shrunken ghosts.

Table 1. ACCELERATION OF GLUCOSE EQUILIBRATION WITH PROGRESSIVE DEPLETION OF GHOST CONTENTS

Half-times estimated from Ørskov's recordings. Vols. refer to average single cell or ghost. $C_s = 0{\cdot}285$; glucose initially all in medium. k given on basis that $K = 0{\cdot}02$ isotone

Preparation	Total vol. (μ^3)	Water vol. (μ^3)	$t_{1/2}$ (min.)	k (isotones per min.)
Intact cells	95	68	0·86	1·51
Ghosts, from lysis at ratio				
1:2·5	62	45	0·65	2·0
1:4·2	43	32	0·41	3·2
1:8·3	33	25	0·30	4·3
1:16·7	24	19	0·23	5·7
1:33·3	17	13	0·18	7·2

This finding, that glucose was equilibrated in the ghosts at about the absolute rate expected from continued operation of the transport system of intact cells, made it highly unlikely that any other mode of transfer of sugar had come significantly into play. (Moreover, all these preparations retained the characteristic of intact cells of total impermeability to *m*-inositol, a cyclic hexahydric molecule physically similar to glucose.) The conclusion was further examined by study of the kinetics; Table 2 shows the similarity in the degree of slowing of glucose exit, in ghosts and cells, brought about by increasing the sugar concentration in the critical range. Had this equilibration occurred by way of uncomplicated diffusion, $t_{1/2}$ would be nearly invariant at all sugar concentrations, and K could be said to be very high (indefinitely greater than 10). But Table 2 shows the much lower K's at which the $t_{1/2}$ data give minimal dispersion in graphical fitting to equation (1); the K value for the ghosts is within the range generally reported for intact cells. It appears to be somewhat higher than that of the paired cell-suspension in the parallel experiment; but since these K's are approaching the lower limit for meaningful resolution by this technique and are subject to an uncertainty of perhaps one-third, no serious evaluation can, at present, be given to this possible minor shift in the affinity constant.

Table 2. GLUCOSE EXIT FROM CELLS OR GHOSTS AS FUNCTION OF C_s
Prior equilibration $C_s = 0{\cdot}5$. Average ghost vol. = 46 per cent of average cell vol.

C_s (isotones)	Cells, $t_{1/2}$ (min.)	Ghosts, $t_{1/2}$ (min.)
0·009	0·24	0·10
0·022	0·36	0·16
0·034	0·59	0·20
0·051	0·74	
0·073	1·03	0·33
K (isotones)	0·014	0·024
k (isotones/min.)	1·8	3·5

The adequacy of these extensions of the indirect Ørskov technique was supported by direct chemical studies. Serial analyses of ghosts and cells in thick suspensions, during equilibration at 37° C. with glucose[6], gave a ghost k of 2·61 isotones/min. (again taking K as 0·02 isotone), while that for the intact cells was 1·65; in this instance the ghosts had sustained an average loss of 71 per cent of the original hæmoglobin, 46 per cent of the water, 49 per cent of the cell volume, and 95 per cent of the K^+, of which 25 per cent had been replaced by Na^+. The persistence of the specific transport activity after such radical alteration of the internal aqueous compartment argues strongly against the notion that the selective permeation is determined by the organization of a protoplasmic–water 'matrix', and points to the surface membrane as the locus of the specific reactive sites.

Membrane transports previously reported as surviving in the erythrocyte ghost under appropriate conditions include K^+ accumulation[11] and glycerol-mediated transport[10]. The former depends on supply at the time of lysis of a combination of metabolites serving later to energize the cation 'pump'; so that it is difficult to establish a fair basis for comparing its capacity in the ghost with that in the intact cell. Glycerol transfer, however, is not thought to involve such complications, and would be expected to show the same reciprocal relation of equilibration-rate to residual ghost volume as noted here for glucose transfer. Stein's finding[10] of a rather small increase in $t_{1/2}$ for entry of glycerol into ghosts, as compared with cells, appears to run counter to this expectation; however, the residual volume of these ghosts was not specified.

This work was supported by the U.S. Atomic Energy Commission.

SEPARATION AND *IN VITRO* CULTURE OF CELLS FROM LIVER TISSUE

By DR. JUSTINE S. GARVEY

Division of Chemistry and Chemical Engineering, California Institute of Technology, Pasadena, California

A CELL-CULTURE examination was initiated to investigate more directly the role of the liver in the immunological response of rabbits to injection of antigen[1,2]. This involved the development of certain cell-culture techniques for the liver.

Most *in vitro* methods[3–9] for liver tissue have not involved separation of the reticulo–endothelial from the parenchymal cells although there have been a few such reports[10–12]. It is of distinct advantage to have separate cultures of the two types of cells, and in order to accomplish this, selection was made both in the initial isolation of cells and in the use of two different growth media. Sterility was observed throughout the following procedures, and solutions were warmed to 37° C. before use, unless indicated otherwise. A normal adult rabbit was bled from the heart, then killed by an injection of air. The abdominal area, which had been previously shaved, was swabbed with tincture of iodine, followed by ether. An incision was made and the liver removed. One lobe was perfused immediately (for parenchymal cell preparation), whereas the remaining tissue (for reticulo–endothelial cell preparation) was placed in 0·3 per cent trypsin prepared in GKN solution (8·0 gm. sodium chloride, 0·4 gm. potassium chloride and 1·0 gm. glucose in 1 litre distilled water).

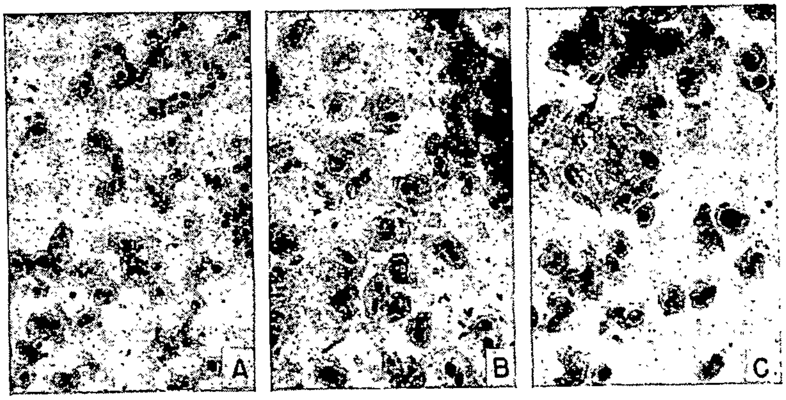

Fig. 1. Parenchymal cell culture from normal adult rabbit. *A*, 5 days after inoculation; *B* and *C*, both 10 days after inoculation. For all three fields, high-power object. × 43, oculars × 10, and photographic enlargement ~ × 10. Total magnification of *c.* 1,800 with emphasis of the fact that *A*, *B* and *C* are entirely comparable magnification

Preparation and Study of Parenchymal Cells

The blood appeared to be entirely displaced by allowing 500 ml. of GKN solution to circulate through one separated lobe, the perfusion fluid being injected directly into the blood vessels through a hypodermic syringe needle.

As a final perfusion, the lobe of liver was injected with about 10 ml. of the culture medium ; this was 6 per cent 'Hyprotigen', an enzymatic hydrolysate of casein in aqueous solution (pH 6·7), containing 0·05 M sodium chloride plus 0·20 M potassium chloride. ('Hyprotigen' is the trade mark of Don

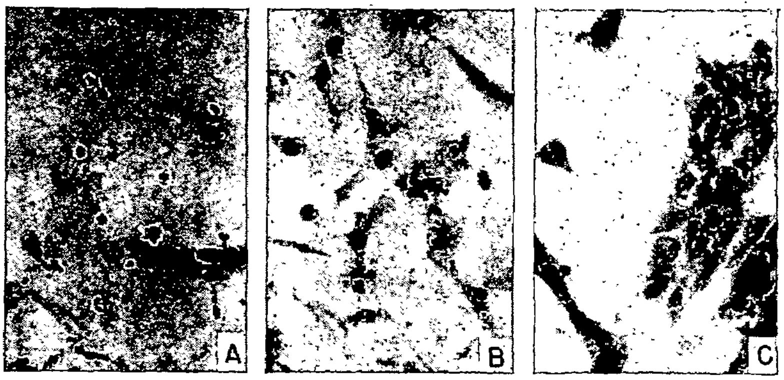

Fig. 2. Reticulo-endothelial cell culture from normal adult rabbit liver. *A*, 1 day; *B*, 3 days; *C*, 5 days after inoculation. Comparable total magnification of *c*. 1,800 for all three fields

Baxter, Inc., Glendale, California; it is supplied also by some international licensees.) This lobe was allowed to incubate for 5–6 hr. in a beaker containing the same medium, placed in a 36–37° C. humidified incubator with a 5 per cent carbon dioxide in air atmosphere. At the end of the incubation the lobe was transferred to a large Petri dish (150 mm. diameter × 20 mm. height) containing about 40 ml. of the medium. For use in dispersing cells, stainless steel cloth (30 mesh, type 304) was fabricated into two rectangular pieces, each 10 × 4 cm.; three horizontal rows of wire were removed from one 4-cm. side and the other 4-cm. side was bent under as a 2-cm. flap for easier handling. The ends from which the wire was removed were placed into the tissue, one to grip the tissue and the other to be used as a rake to release the cells into the medium. A small area was 'raked' to give almost complete dispersion of the cells, then other adjacent areas of tissue were processed similarly until only connective tissue and blood vessels remained in an otherwise homogeneous suspension of cells. The former were discarded as debris and the cell suspension was placed in an Erlenmeyer flask from which equivalent aliquots were pipetted into 15-ml. conical, graduated centrifuge tubes.

These tubes were centrifuged for 4 min. at 650 r.p.m. (50*g*) in a clinical centrifuge with trunnion head. The supernatant was discarded and the pellet was used to prepare replicate cultures of 1/3 ml. packed cells per 5 ml. medium in Petri dishes of 60 mm. diameter × 15 mm. height. These dishes contained a glass coverslip. A zero-time smear of the inoculum was examined with Wright stain, whereas a May–Grünwald Giemsa stain was used for cultures obtained at various times after incubation in the humidified 5 per cent carbon dioxide in air atmosphere where temperature was regulated at 36–37° C. The stained smear showed that the inoculum consisted of parenchymal cells with no other cell type being obvious; the majority of these cells were binucleated. After 3–5 days the cultures differed from those incubated for a shorter time both in number of cells and in the pattern of growth, that is, instead of a few isolated cells, there were fairly large groups of cells, and the cytoplasm was spreading, frequently as strands between the cells (Fig. 1, *A*). A determination of nitrogen in washed cells showed a slight increase after 5 days in culture, and at 10 days the nitrogen value had doubled compared with that for the inoculum. At 10 days there occurred amitotic activity in some areas of all cultures. The nuclear volume increased conspicuously, and the shape of the nuclei varied greatly (Fig. 1, *B* and *C*). These observations differ from those reported previously for liver tissue in culture but confirm quite precisely a discussion of amitotic activity as observed in human adult tissue just following autopsy[13].

Preparation and Study of Reticulo-Endothelial Cells

As soon as the perfused lobe was incubated, as noted above, the tissue which had been placed in trypsin was cut into pieces about 2–3 mm.[3]. With a pipette as much solution was removed as possible, and the tissue was transferred into an Erlenmeyer flask containing 100 ml. 0·01 per cent collagenase[14,15] prepared in GKN and cooled to 10° C. The suspension of tissue was stirred magnetically during refrigeration for 3 hr. The supernatant was poured from the tissue and 50 ml. trypsin was added. The pieces of tissue, suspended in trypsin, were stirred for 20 min. with an air-driven magnetic stirrer in the 36–37° C. incubator. It was very apparent that the enzyme treatment had reduced the tissue to a turbid suspension and connective tissue. The connective tissue was removed and the suspension of cells was centrifuged at 1,650 r.p.m. (330*g*) for 4 min. The supernatant was discarded and the pellet was washed twice in serumless medium (Table 1) for 4-min. periods at 1,650 r.p.m. (330*g*). About 1/3 ml. of pellet was inoculated per 5 ml. medium (Table 1)

Table 1. TISSUE CULTURE MEDIUM FOR RETICULO-ENDOTHELIAL CELLS

The quantities of amino-acids were derived as relative ratios from an analysis of the composition of rabbit antibodies (ref. 16), the remaining formulation developed from various experiments with splenic cultures, which do not differ significantly from reticulo-endothelial liver cell cultures

Amino-acids	Mgm./l. complete medium	Vitamins	Mgm./l. complete medium
l-Arginine (HCl)*	12·20	Choline chloride	4·0
l-Cysteine (HCl)*	8·14	Folic acid†	4·0
l-Cystine†	3·13	Nicotinamid	4·0
l-Histidine (HCl)*	3·79	Calcium pantothenate	4·0
*dl-Iso*leucine	17·56	Pyridoxal (HCl)*	4·0
l-Leucine	15·80	Thiamine (HCl)*	4·0
l-Lysine (HCl)*	16·15	Riboflavin	0·4
l-Methionine	2·80		
l-Phenylalanine	10·98		
l-Threonine	26·44		
l-Tryptophan	5·40		
l-Tyrosine‡	13·24	Salts and carbohydrate	Mgm./l. complete medium
dl-Valine	40·88		
l-Thyroxine		NaCl	6,400
(sodium salt)	0·025	KCl	400
l-Glutamic acid	23·60	$NaH_2PO_4 \cdot H_2O$	125
dl-Alanine	22·72	$CaCl_2$	200
l-Aspartic acid	19·34	$MgSO_4 \cdot 7H_2O$	200
Glycine	11·44	$Fe(NO_3)_3 \cdot 9H_2O$	0·1
l-Proline	17·12	$NaHCO_3$§	3,700
l-Serine	21·84		
Inositol	7·00	Dextrose	4,500

* Crystallized in hydrochloric acid.
† Dissolved in 1 ml. 1 *N* sodium hydroxide.
‡ Dissolved in boiling water.
§ Dissolved separately, then added to other salts.

The complete medium is prepared by combining in a 1-litre volumetric flask the solutions which are prepared separately, namely, the amino-acids in about 200 ml., vitamins in about 100 ml., salts and dextrose in about 500 ml. Then 1·5 ml. 1 per cent phenol red is added. The volume is diluted to 1 litre, flushed with carbon dioxide until colour becomes orange. The solution is sterilized in '02 Selas', dispensed in aliquots and refrigerated for use over a period of 2–3 months. Just prior to use in cultures, the following are added to the final concentration indicated:

Rabbit serum (optional)	150 ml./l. = 15 per cent
Insulin	0·5 mgm./l., that is, 11 units
l-Glutamine	292 mgm./l.
Penicillin	10^5 units/l.

which contained 15 per cent normal rabbit serum. The maximal contamination with parenchymal cells was estimated to be 1 per cent of the inoculum. After 1 day (Fig. 2, *A*) considerable differentiation of cells was observed in stained cover-slip cultures, and conspicuous morphological change and growth had occurred after 3 and 5 days (Fig. 2, *B* and *C*). After 10 days, there was a sheaf of cells of the type that predominated in the culture at 5 days, and these showed rather frequent mitotic figures.

Reproducibility with all the above techniques was easily achieved. The commercially available medium 'Hyprotigen', containing mostly peptides and some amino-acids, was chosen for growing parenchymal cells as a result of screening various media. With regard to the medium described in Table 1, although this was less satisfactory for parenchymal cells than was the 'Hyprotigen', the omission of serum and addition of salmine protamine sulphate improved somewhat the cultural characteristics. It should be emphasized that a parenchymal cell culture does not require serum and, in fact, is inhibited by the presence of unmodified serum. Whereas peptides and amino-acids suffice for growth of parenchymal cells, the reticulo–endothelial cell culture does have an apparent requirement for serum. The rather general failure in the past with cultures of liver tissue may be largely attributed to the fact that it is extremely difficult to attain optimal conditions for a mixed cell population, and the more slowly growing parenchymal cell is rather rapidly suppressed by the reticulo-endothelial cell which differentiates and assumes fibroblastic characteristics.

These investigations are being continued with particular emphasis given to the parenchymal cell culture which slowly metabolizes, with secretion of protein into the medium, while demonstrating a characteristic amitotic activity.

Special acknowledgment is given to Prof. Dan H. Campbell for critical discussions and encouragement during the investigation. The financial support of the U.S. National Institutes of Health is appreciated.

PHOTOPERIODIC EFFECTS ON STOMATAL BEHAVIOUR IN *XANTHIUM PENNSYLVANICUM*

By DR. T. A. MANSFIELD and PROF. O. V. S. HEATH, F.R.S.

University of Reading, Horticultural Research Laboratories, Shinfield Grange, Shinfield

DIFFERENCES in stomatal behaviour under different photoperiodic treatments were reported by Schwabe[1] for *Chrysanthemum* and *Kalanchoe blossfeldiana*. He found that with short days (8 hr. daylight + 16 hr. darkness) opening of the stomata occurred towards the end of the night, but with long days (8 hr. daylight + 8½ hr. low light + 7½ hr. darkness) no night opening occurred.

We have investigated the relationship between photoperiodic treatment and stomatal behaviour using the short-day plant *Xanthium pennsylvanicum*. In some preliminary experiments effects similar to those reported by Schwabe were found: under short-day conditions (16 hr. nights) the stomata were closed for the first 11–12 hr. in the dark, but then began to open slightly. This opening was relatively small compared with that in high-intensity light (20,000 lux) during the day. In long-day conditions, in which the 16-hr. night was replaced by 8 hr. of low-intensity illumination (1,500 lux) followed by 8 hr. darkness, night opening did not occur. Light of 1,500 lux given after high-intensity light was not sufficient to maintain any appreciable opening, and consequently, under the conditions of these experiments, the stomata were closed for a larger proportion of the 24-hr. cycle in long days than they were in short days.

Considerable differences were observed in the rate of stomatal opening in light in the morning under different photoperiodic treatments. A detailed investigation has revealed a close relationship between the rate of opening in light and the length of the preceding night. In Fig. 1 it is shown that stomatal opening was much more rapid after 9-hr. than 7-hr. nights. The day-time illumination was 20,000 lux; the 9-hr. and 7-hr. treatments were, respectively: (*a*) 7 hr. of low light (1,500 lux) at the end of the day, followed by 9 hr. of darkness; (*b*) 9 hr. of 1,500 lux at the end of the day, followed by 7 hr. of darkness. It is interesting that 8½–9 hr. is the critical long night for flowering in *X. pennsylvanicum*. In a factorial experiment designed to study the interaction of length of night and the intensity of the light used to shorten the night, similar results to the above were obtained using either 160 or 40 lux, and even 10 lux had a significant effect in reducing subsequent rate of stomatal opening if given for 15 hr. followed by 1 hr. darkness. In another experiment, rate of opening after nights ranging in length from 1 to 23 hr. was examined; the different lengths of night were achieved by providing different periods of light of 1,500 lux at the end of the day, shortening a 24-hr. dark period. An almost complete cycle of 'opening ability' was found (Fig. 2).

In conjunction with these measurements, observations were made on the occurrence of night opening of the stomata. During a long period of darkness the stomata were first of all closed completely, but after several hours they opened slightly, remained open for about 12 hr., and then closed again. The most important factor controlling the timing of this cycle of events was the time of termination of the low-intensity light. This is illustrated in Fig. 3, in which are recorded the times of the beginning of night opening under different illumination treatments. The plants had received high-intensity illumination (20,000 lux) until 4 p.m., and then various periods of low light terminating at the times shown. Prolonging the illumination delayed the occurrence of night opening, as indicated by the significant regression (continuous line). The broken line is the relation that would be expected if prolonging the low light by a given period had displaced the time of opening by the same period. The observed relation was significantly different from this ($P < 0{\cdot}001$), showing that the time from the termination of light to the commencement of opening was somewhat shorter after a longer period of low light. This indicated that the dark processes could go on in light of 1,500 lux, though at a reduced rate. The foregoing experiments were carried out at 27° C. In an experiment on the interaction of light and temperature it was found that in darkness night opening began sooner the lower the temperature in the range 15°–36° C.; in light of 10 lux it did not occur at all within 20 hr. of the change from 20,000 lux at 36° or 29° C., was delayed 1½ hr. at 22° C. and began at the same time as in darkness (after 9½ hr.) at 15° C.

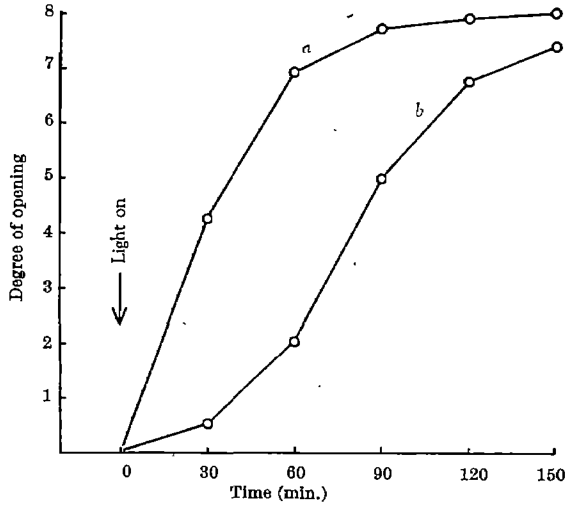

Fig. 1. Stomatal opening in light of 20,000 lux: *a*, after 9-hr. night; *b*, after 7-hr. night. Each curve is the mean from observations on six separate leaves. Ordinate scale, arbitrary units of total pressure minus pressure across the leaf, in a resistance porometer, that is, increasing values indicate opening

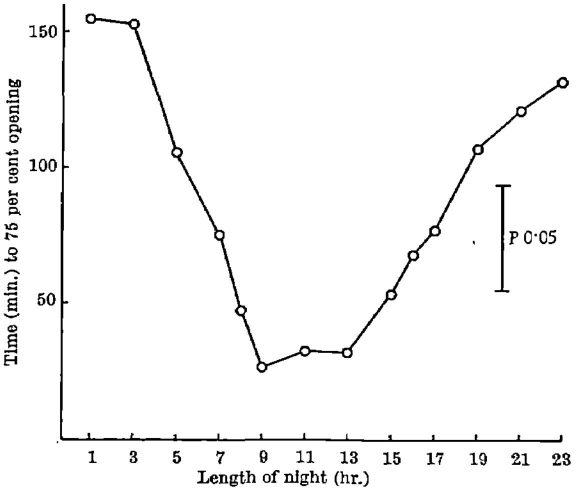

Fig. 2. Stomatal opening in 20,000 lux after different lengths of night. The time (min.) from the start of illumination to the attainment of 75 per cent of full aperture is shown. Each value is the mean of six observations on separate leaves. The least significant difference for comparison of two means at P 0·05 is indicated

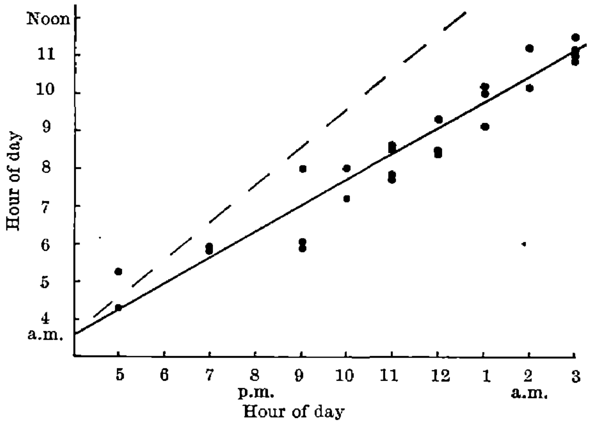

Fig. 3. Control of night opening of the stomata in *X. pennsylvanicum* by the time of termination of illumination. Ordinate, time of first detectable night opening. Abscissa, time of termination of light of 1,500 lux

We have been able to conclude that the differences in rate of opening in light after different lengths of night are related to the tendency for the stomata to open slightly for a time in continuous darkness. When they are already in the night-opening condition, however slight this opening may be, the rate of opening in light is very greatly increased.

The most satisfactory explanation of these observations would seem to be that an endogenous rhythm of 'opening ability' occurs in the stomatal cells in the dark, and that the phase of this rhythm is set mainly by the time of transition from light to dark, in much the same way as it was, for example, in the rhythm of carbon dioxide output in *Bryophyllum fedtschenkoi* reported by Wilkins[2]. We have not yet, however, shown that there is a true rhythm in which the cycle is repeated, though there has been some evidence of this in other species[3,4].

A full description of these and other findings will be published in due course, and an attempt will be made to relate them to theories of the stomatal mechanism. The results suggest that dark fixation of carbon dioxide might be concerned; this is known to occur in *X. pennsylvanicum*[5]. This aspect is being investigated.

The data were collected for attached leaves on potted plants using a new recording resistance porometer which automatically detaches and replaces *seriatim* the lower portions of the porometer cups on four leaves; the leaf surfaces within the cup areas were thus freely exposed to ambient air of normal carbon dioxide content except during the actual readings. This apparatus will be described elsewhere.

This investigation was carried out during the tenure by one of us (T. A. M.) of an Agricultural Research Council postgraduate studentship.

INFLUENCE OF ELECTRICAL FIELD ON PUPATION AND OVIPOSITION IN *NEPYTIA PHANTASMARIA* STKR. (LEPIDOPTERA: GEOMETRIDAE)

By DR. D. K. EDWARDS
Forest Biology Laboratory, Federal Building, Victoria, British Columbia

IT is known that weather often can affect insect behaviour and development profoundly. Electrical factors associated with weather may be partly responsible for these biological reactions[1], but very little experimental work has been done to determine if an electrical field can influence insect behaviour and development. Avio and Tarozzi[2] studied *Drosophila* oviposition in an electrical field (125 V./m.) but found no significant effects. More recently, Levengood and Shinkle[3] reported higher yields of *Drosophila* progeny reared in an electrical field. They did not mention, however, whether there was an observable effect of the field on time of development. Edwards[4] has reported some observations on the behaviour of adult *Calliphora* and *Drosophila* in an electrical field, with *Drosophila* responding to establishment of the field by temporarily reducing its activity.

Electrical field effects on the development of Lepidoptera, and on the location of eggs deposited by insects, have not been reported previously. Accordingly, some tests were made to determine whether an electrical field could influence pupation-time and the number and location of eggs deposited by moths of the phantom hemlock looper, *Nepytia phantasmaria* Stkr. This moth has one generation a year, and the adults live for about five days in the laboratory.

Four wooden boxes, 22 × 25 × 34·2 cm., contained the insects. Each box was covered on one side with a plastic screen and on the opposite side with a sliding glass wall. The boxes were placed on end, so that the glass wall could be opened slightly at the bottom by sliding it upwards. Inside, on the bottom of each box, an aluminium 'field plate', 19 × 14 cm., was suspended horizontally by two glass jars 4·5 cm. high. Directly beneath the plate, a plastic tray, 16 × 7·5 cm., with walls 2 cm. high, was placed between the two jars, and its inner bottom surface was covered with aluminium foil. The foil was connected to an insulated wire running through the box wall to the earthed negative terminal of an 810-V. battery-pack. The field plates in boxes I and II were each attached to an additional insulated wire passing through the box wall. For box I, the distal end of the field-plate wire was connected directly to the positive terminal of the battery-pack, thus establishing an electrical field (180 V./cm.) between the tray and the plate. A time-switch which alternated 'on' and 'off' periods of 5-min. duration (so than an intermittent field was established) was connected to the box II field-plate wire, between the box and the battery-pack. The field plates in boxes III and IV were wired directly to the trays ; hence, there was no field between the plate and tray in these boxes. Boxes I and II were placed on top of boxes III and IV, and the unit of four boxes was illuminated continuously by a 60-W. bulb placed 8 ft. from the screened sides, so that all had approximately the same distribution of light.

Penultimate-instar larvæ were collected from Douglas fir in an outdoor cage, and allowed to pupate in the laboratory. Because all the insects did not pupate at the same time, it was necessary to add pupæ to the experiment on four different dates. Equal numbers of 1- to 2-day-old pupæ were put into each tray on August 8, 10, 12 and 15, to give a total of 98 pupæ in each box. Emergence, which began on August 22, was recorded daily by removing carefully the tray from each box through the sliding glass wall and counting the empty pupal cases.

The central portion of the *S*-shaped emergence curve was treated as a straight line, and a line was calculated for each set of emergence data by the method of least squares. The equations for the lines are : Box I : $Y = 12{\cdot}41 + 10{\cdot}53X$ ($\bar{x} = 3$; $\bar{y} = 44$). Box II : $Y = 18{\cdot}17 + 10{\cdot}75X$ ($\bar{x} = 3$; $\bar{y} = 50{\cdot}42$). Boxes III and IV : $Y = 19{\cdot}34 + 11{\cdot}10X$ ($\bar{x} = 3$; $\bar{y} = 52{\cdot}64$). The slopes of the lines did not differ significantly. An analysis of variance showed the emergence curve for insects in box I (constant electrical field), to be significantly later than the curve for the combined data from the control boxes III and IV ($P < 0{\cdot}01$). The 50 per cent emergence point for box I was slightly less than one day later than the control value. The line for box II insects (interrupted field) although shifted slightly towards a later time, does not differ significantly from the control curve. Table 1 shows that there were more males than females in all boxes, with the greatest difference in box I. However, the lag in the emergence from box I is not a result of the presence of these extra males. In fact, since males emerge somewhat before females in *Nepytia*, their predominance in box I should shift the emergence curve forward, not backward, in time. In other words, the significant shift occurred, despite the presence of more males.

Later, eggs deposited by the adults on all parts of the box, tray, and field plate were counted in each box. These data, together with pupal mortality and the numbers of each sex, are shown in Table 1. The mortality, although very low, was greatest in box I. There were also somewhat fewer eggs per female laid in boxes I and II than in the control boxes. The most definite difference, however, appeared in a comparison of eggs laid on the under-surfaces of the field plates with those on the upper surfaces of the plates. Chi-squared tests showed a significantly smaller percentage of eggs laid on the under-surfaces in boxes I and II than in boxes III and IV ($P < 0{\cdot}01$), with box I differing most from the controls. Where there was no field (boxes III and IV) the majority of the field-plate eggs were deposited on the under-

(*Continued on page 993*)

Table 1. *Nepytia* MORTALITY, NUMBERS OF INDIVIDUALS, AND NUMBERS OF EGGS DEPOSITED ON FIELD PLATE AND THE REST OF THE BOX, IN BOX I (CONSTANT FIELD), BOX II (INTERRUPTED FIELD), AND BOXES III AND IV (NO FIELD)

	Box I	Box II	Box III	Box IV
Mortality	3	1	1	0
Males	62	54	55	50
Females	36	44	43	48
Total	98	98	98	98
Total eggs	1,330	1,661	1,991	2,039
Eggs/female	36·94	37·75	46·30	42·47
Eggs on field plate	84	128	281	155
Eggs/female on field plate				
Upper surface	1·44	1·06	0·65	0·47
Under surface	0·88	1·84	5·88	2·75
Per cent on under surface	37·93	63·44	90·04	85·40

surfaces of the plates. This is probably related to the fact that *Nepytia* normally deposits most of its eggs on the under-surfaces of fir needles. In the boxes where an electrical field was present beneath the field-plate, however, and especially in box I where the field was continuously present, oviposition on the under-surfaces of the plates was conspicuously reduced. The field was very much more intense beneath the plate than above it, since the field was established between tray and plate. It was not possible to make a comparison of the numbers of eggs laid on the under-surface of the roofs of the boxes, since the numbers varied greatly between boxes.

These results show that the development of *Nepytia* pupæ, and also the number and location of eggs deposited by the adults, can be influenced by an electrical field. The magnitude of the experimental field was 180 V./cm. Fleming[5] states, "When the [thunder] cloud is within a few km., the pre-discharge field ranges from 10,000 to 30,000 volts per meter . . ." (p. 659). Thus, the intensity of the experimental field was not unreasonably high, compared with that found in Nature. However, a steadily maintained field of 180 V./cm. would probably not be found in natural atmospheric conditions, because fields associated with storms fluctuate markedly. The intermittent experimental field of 180 V./cm. in box II, which was somewhat closer to the natural situation, did not have as great an effect as the steady field. But the more intense experimental conditions were necessary in order to determine what kinds of effects to expect from application of a field, and what direction these might take.

I am indebted to W. G. Wellington and R. E. Foster of this Laboratory, for criticism of the manuscript and aid with the statistical analysis, and to H. S. Burr, Yale University School of Medicine, for his suggestions.

MELANISM IN CAPTIVE WEAVER-FINCHES (*QUELEA QUELEA*)

By DR. B. LOFTS

Department of Zoology and Comparative Anatomy, St. Bartholomew's Hospital Medical College, University of London, E.C.1

THE red-billed dioch, *Q. quelea*, is a weaver-finch which occurs in enormous numbers in Africa. Large, nomadic flocks roam the countryside in search of food and do enormous damage to crops and timber. The species has a wide distribution coinciding with the 30-in. rainfall isohyet[1]. It is sexually dimorphic: before the breeding season the male assumes a vivid nuptial plumage which temporarily distinguishes it from the permanently drab female (Fig. 1*a* and *b*). During the eclipse season, however, this cock plumage (black facial mask and light gold crown and breast) is shed and both sexes wear the same modest hen plumage, becoming morphologically indistinguishable.

During the course of a recent investigation of the breeding biology of this species[2], it was noted that some of the birds developed a black plumage. The birds, which had been flown from Africa, were housed in a large aviary under a constant photo-period of 12 hr. and a temperature of 65–75° F. Within three months of their arrival in London, some of the birds had become noticeably darker. In these specimens the entire plumage had been affected and became darker with each successive moult, until eventually the whole bird was black (Fig. 1*c*). The melanism occurred in both sexes and was common to eclipse and breeding periods.

Melanic males did not resume the typical nuptial dress during the breeding season and gave no external indication of coming into breeding condition. Autopsy revealed, however, enlarged testes of maximum size filled with bunched spermatozoa. Female *Quelea* normally demonstrate a change of beak colour during the breeding season. In the contra-nuptial period both males and females possess bright red bills, but those of the latter sex change to pale yellow when the nuptial season starts. This colour cycle was unaffected by the assumption of a melanic plumage, and during the breeding period black females were easily distinguishable from melanic males by their yellow bills (Fig. 2*a* and *b*).

During their first year of captivity, about 8 per cent of the birds (about 40 specimens) became melanic. At the end of a further two years, the proportion of affected birds had risen as high as 30–40 per cent. Mr. D. C. Lourens, chief of the Division of Entomology, Department of Agricultural Technical Services, Pretoria, South Africa, has reported (personal communication) that 75 per cent of his captive *Quelea* have undergone a similar process of melanization to that described above.

So far as I am aware, melanic *Quelea* have never been seen in the wild and only appear as a result of captivity.

In order to investigate this phenomenon and determine what artificial factor or factors might produce it, groups of *Quelea* (50 specimens) were subjected to the following conditions:

Photoperiodicity	
Group I	8 hr. day-length
„ II	12 hr. „
„ III	17 hr. „
Temperature	
Group IV	50° F. room temperature
„ V	70° F. „ „
„ VI	95° F. „ „

All the birds were fed on the same seed mixture and were kept under the above conditions for a period of four months (August–November), during which time they underwent a moult into breeding plumage. Groups I–III were all maintained at a constant room temperature of 70° F., and groups IV–VI had a uniform photo-period of 12 hr. In all groups the melanic birds were unaffected; but some of the specimens which had started in normal eclipse plumage moulted into a nuptial plumage showing signs of melanism.

In order to determine whether the quality (rather than the photoperiod) of the artificial light (fluorescent tube) may have been a contributory factor, advantage was taken of a period of mild sunny weather to expose melanic *Quelea* to sunshine. This resulted in the birds (four male specimens) reverting back to normal within the first moult. The birds were placed in an outside cage during the first week of May and all moulted to a normal eclipse condition.

One main difference in the quality of sunlight and artificial illumination is the reduction in the amount of ultra-violet in the latter. Recently, Lourens has been able to show that captive *Quelea* given a daily dose of ultra-violet light do not become melanic, whereas unexposed captive birds do. In the present investigation, 10 melanic *Quelea* were exposed to ultra-violet from an ordinary sun-ray lamp at a distance of 8 ft. from their cage. They were given two 8-min. sessions a day throughout one month while they were moulting. When feather regeneration had been completed, seven had assumed a normal nuptial dress (Fig. 3*a* and *b*), and three, though still melanic, had assumed a much lighter plumage.

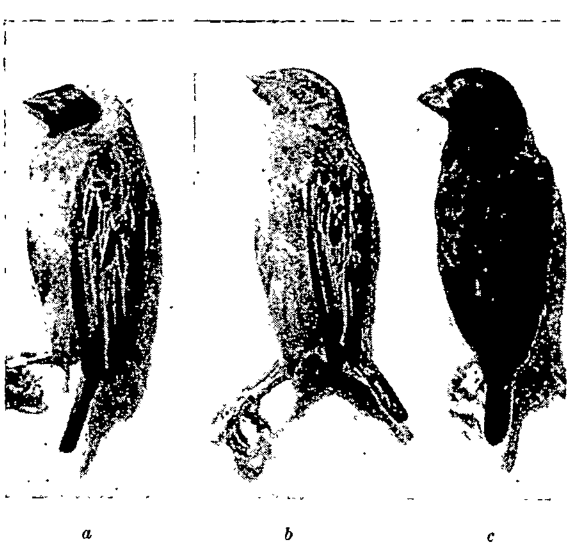

Fig. 1. (*a*) Male *Quelea* in nuptial plumage. (*b*) Female bird during breeding season. (*c*) Melanic female

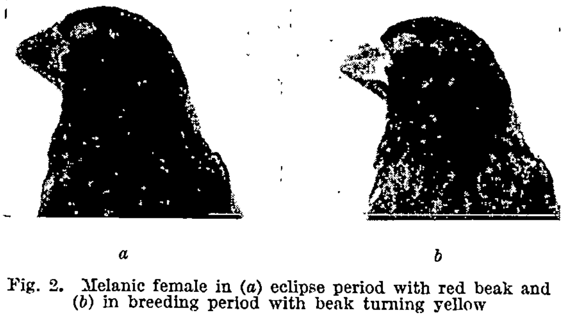

Fig. 2. Melanic female in (*a*) eclipse period with red beak and (*b*) in breeding period with beak turning yellow

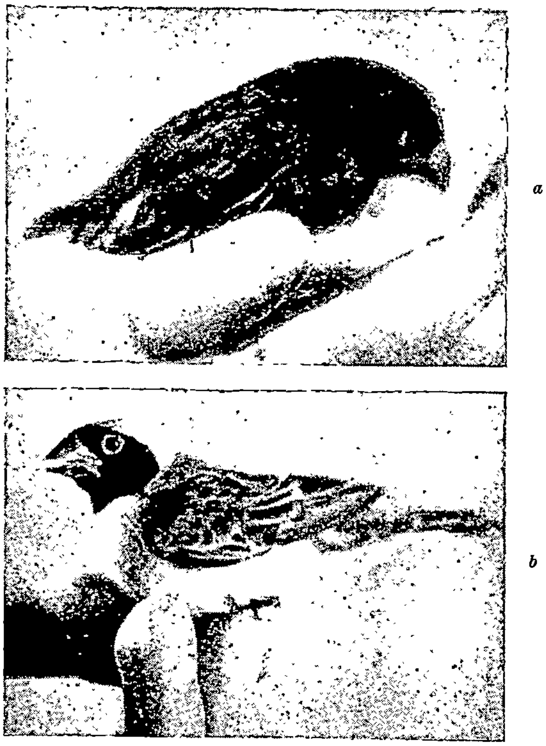

Fig. 3. Effect of exposure to ultra-violet light. (*a*) Melanic male before moult. (*b*) Same bird after exposure to ultra-violet light during moult

It is not known how the ultra-violet rays exert their influences on pigmentation in growing feathers. The cyclical assumption of a breeding plumage in this and other weaver finches is under the direct control of the pituitary[3] and, in particular, is responsive to the output of luteinizing hormone[4]. This hormone cannot be responsible for the phenomenon described in the present work, however, since all the plumage is affected, whereas luteinizing hormone will only stimulate the deposition of melanin in those regions where it is normally found in the nuptial plumage, namely, the black facial mask. It seems not impossible that the ultra-violet influence may be imposed directly on the organizing feather follicle during growth of plumage.

I thank Mr. D. C. Lourens for his kindness in allowing me to refer to some of his unpublished results. This investigation was assisted by a grant from the Nuffield Foundation.

PHYSICS

Interaction of 14-MeV. Neutrons with a Silicon Semiconductor Nuclear Particle Detector

THE recent development of silicon semiconductor nuclear particle detectors has provided a convenient method for studying the charged particles emitted from the interaction of neutrons with silicon.

A silicon surface barrier detector, manufactured from 400-Ω cm. *n*-type silicon, was irradiated with neutrons of energy 14·03 ± 0·05 MeV. from the reaction $T(d,n)^4He$. Pulses from the detector, which was operated at a reverse bias of 50 V., were amplified by a charge-sensitive low-noise pre-amplifier and a modified 1430 Harwell linear amplifier and then analysed by a 400-channel *RIDL* pulse-height analyser. Fig. 1 shows a typical energy spectrum observed.

Assuming that reactions induced in silicon-28 (92 per cent abundant) are the most important then the possible charged-particle emitting reactions are $^{28}Si\ (n,p)\ ^{28}Al$, $Q = -3{\cdot}86$ MeV.; $^{28}Si\ (n,\alpha)\ ^{25}Mg$, $Q = -2{\cdot}66$ MeV., and $^{28}Si\ (n,d)\ ^{27}Al$, $Q = -9{\cdot}36$ MeV. The (n,p) and (n,α) reactions have been observed by Dearnaley and Whitehead[1] using 6·3-MeV. neutrons.

Calculation of barrier depth and comparison with range-energy values for protons and α-particles shows that unless the high-energy protons are emitted along the plane of the detector, they will escape from the sensitive volume of the detector whereas the maximum-energy α-particle range is much less than the barrier depth, and thus, apart from edge effects, all the α-particles emitted will be detected. Hence, one would expect a greater contribution to the observed spectrum from (n,α) than from (n,p).

Using the results of Hinds and Middleton[2] for the energy-levels of magnesium-25 and the energy-level scheme for aluminium-28 given by Endt and Braams[3], we calculated the expected energy of proton groups corresponding to the first seven levels in aluminium-28 and α groups corresponding to the first fifteen levels in magnesium-25. In Fig. 1, the arrows indicate the position of these groups and it will be seen that the position of the observed groups corresponds very closely with those expected from the (n,α) reaction and that there is little evidence for the (n,p) reaction under these conditions.

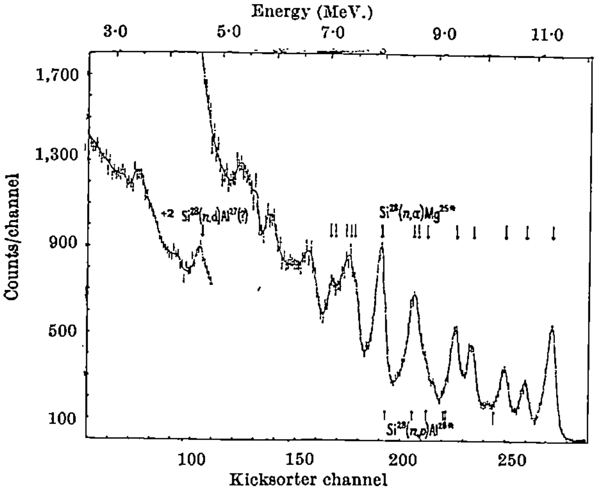

Fig. 1. Energy spectrum observed from interaction of 14·03 MeV. neutrons with a silicon surface barrier detector

The peak evident at 4·6 MeV. in Fig. 1 has been tentatively assigned on the basis of *Q*-value to the reaction $^{28}Si\ (n,d)\ ^{27}Al$.

Cross-section measurements were made for the α-groups leading to the first five levels of magnesium-25. The results are given in Table 1.

Table 1. CROSS-SECTION FOR REACTION $^{28}Si(n,\alpha)\ ^{25}Mg$

Magnesium-25 (MeV.)	$\sigma(n,\alpha)$ at 14·03 MeV.
0	1·84 ± 0·61 mb.
0·582	0·75 ± 0·25 mb.
0·976	0·98 ± 0·33 mb.
1·612	1·19 ± 0·39 mb.
1·965	1·28 ± 0·43 mb.

Further work is in progress to study the (n,p) reaction and measure the excitation function for the (n,p) and (n,α) reactions.

Magnetic Mirror Confinement of Exploding Wire Plasma

THE exploding wire phenomenon has recently been investigated by several laboratories as a high-density, high-temperature plasma source. For short durations temperatures in excess of 250,000° K. have been observed[1]. Further work has been carried out to confine the exploding wire plasma, making use of its very high current-densities and self-magnetic field[2].

It is the object of this communication to report the production and confinement of exploding wire plasmas in a magnetic mirror configuration. The high current and voltage needed for the exploding wire phenomena may also be used at the same time to produce the magnetic fields necessary for containment of the plasma. Because of the radial particle velocities released by the exploding wire[3], it is possible that a large number of ions will be trapped in an axial magnetic field. By this mechanism of producing a high-density plasma in the central region of a fast-rising, axial magnetic field, large densities of particles may possibly be achieved in the final confined state. In this experiment a capacitor bank of 1·7 μF. was

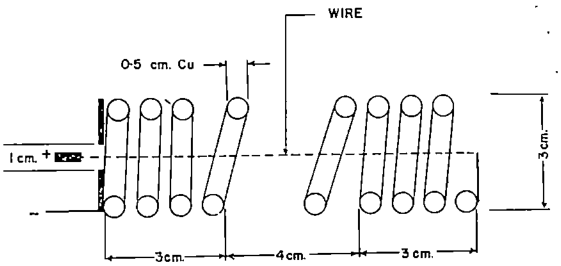

Fig. 1. Axial cross-section of magnetic mirror coil

initially charged to 22 kV. Connexions between the capacitor bank and magnetic mirror coil were made with flat sheet transmission lines, and the capacitor bank was triggered by a three-element spark gap. The capacitor bank has a rise-time of 4 μsec. after the initial triggering. The magnetic mirror coil consists of eight turns of 0·5 cm. diameter copper in the geometry as shown in Fig. 1. The wire to be exploded for producing plasma is shown in Fig. 1 to be on the axis of the coil in a series arrangement. All experiments were carried out in air at atmospheric pressure. The maximum current produced at the first current peak through the system, was estimated to be $1\cdot0 \times 10^4$ amp. This produces a maximum barrier field for the magnetic mirror coil of about 16 kilogauss, and a central field of about 7 kilogauss. A streak camera of the rotating mirror type was used for the observations of the plasma. For all photographs this camera was used at a writing speed of 13·2 μsec./cm., with the same film, at an optical stop of $f/2\cdot5$. The slit of the camera was focused on the central region of the magnetic mirror coil, perpendicular to the wire used for producing plasma. Streak photography was an effective means of recording the width of plasma with time.

Using $C = 1\cdot7$ μF., at 22 kV., and 3 mil copper wire with no external magnetic field, the exploding wire plasma shows the well-known current pause or 'dwell time'[4,5]. A streak photograph showing the 'dwell time' and 'restrike' appears in Fig. 2*a*. The beginning of the first explosion starts at $t = 0$ sec., and the 'restrike', or second current pulse, occurs at 75 μsec. During the time of the 'restrike' the light-emitting portion of the plasma is observed to increase in the radial direction to 4 cm. This pulse is then followed by an afterglow which continued beyond 210 μsec. The streak photograph in Fig. 2*b* was taken with the same conditions as Fig. 2*a* except that the plasma was produced in the central region of the axial magnetic field of the magnetic mirror coil. This streak photograph shows no 'restrike' or second current pulse. The plasma in the axial magnetic field is seen to increase in diameter to 0·75 cm. in 7 μsec., where it then remains with a relatively constant diameter during the remaining 0·01 sec. existence of the plasma. The observed confinement time is found to be increased by 50 per cent by placing a 3 cm. copper disk, with a 1-cm. hole at the centre, at the negative end of the coil as shown in Fig. 1. This disk acted as a switch that shorted the capacitor bank once the plasma had expanded to 1 cm. diameter. Light intensity decreased considerably when placed in the axial magnetic field and streak photography was only possible when high-speed film was used with a fast lens. The appearance of longitudinal striations in the plasma (Fig. 2*b*), when placed in the magnetic field, may possibly be associated with the Kruskal–Schartzschild instability. The plasma never appears to break up but continuously decreases in light intensity until photography is made impossible. The possibility that the plasma may be forming a closed current loop with its own magnetic field running axially along the plasma may explain the long time of confinement from an initially pulsed system. Although most of the work done to date has been mainly qualitative the results warrant further investigation. In the future, magnetic probe studies and other observations will be made in high vacuum.

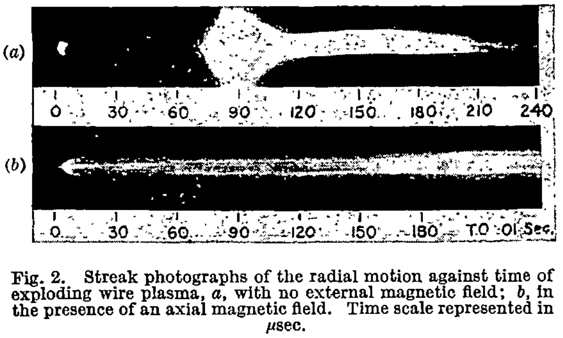

Fig. 2. Streak photographs of the radial motion against time of exploding wire plasma, *a*, with no external magnetic field; *b*, in the presence of an axial magnetic field. Time scale represented in μsec.

I thank Dr. J. D. Fox and Dr. E. A. Desloge for their helpful discussions and criticism, without which this work would have been impossible.

Variation of Anisotropy Axis Dispersion with Thickness of Nickel-Iron Films

Thin films of nickel-iron evaporated in a magnetic field exhibit a uniaxial anisotropy. It has been postulated by West[1] and others that the anisotropy axes in local regions of the film vary in direction about an average axis. This angular dispersion β has been determined by West using magnetoresistance measurements and by Smith[2] with Bitter figure techniques. In the present work the variation of β with film thickness has been measured using an apparatus which has been fully described by Raffel *et al.*[3].

A field pulse H_A, greater than the anisotropy field H_K, was applied along the average difficult direction, and during the latter part of this pulse a small pulse H_D was applied along the average easy direction. The flux change parallel to the easy axis, due to the application of H_A, was measured with a single pick-up loop, and the minimum value of H_D giving full output was taken to be proportional to the maximum value of β. In practice, the approach to full output was too gradual for accurate measurement of this minimum value, and a level of H_D, H'_D say, giving 80 per cent full output, was used. An angle β' given by $\sin\beta' = H'_D/H_K$ therefore gives the maximum dispersion in anisotropy over some 80 per cent of the film. Hence, 20 per cent of the film has hard directions at angles

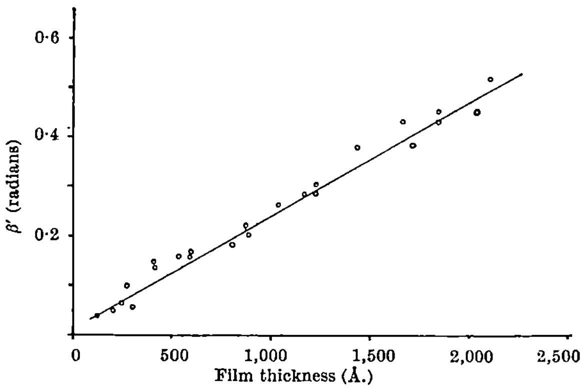

Fig. 1

to the mean greater than β', and 80 per cent at angles less than β'.

The nickel-iron films used in one series of measurements were made in a single deposition, the thickness variation being produced by partially covering the ingot with a shutter. The alloy was deposited from an ingot heated by eddy current, on 0·008-in. thick glass substrates heated to a temperature of 300° C. in an aligning field of 10 œrsteds. The pressure duringn deposition was 10^{-5} mm. mercury, the nominal ingot composition was 82–18 per cent nickel-iron and the deposition took place in some 60 sec. The film thicknesses were measured using Tolansky fringes. The anisotropy field H_K was 3·0 œrsteds and independent of film thickness, while the coercivity H_c varied with thickness in a manner similar to that reported by Methfessel *et al.*[4].

Fig. 1 is a typical graph of β' against film thickness from one such series and shows a linear increase of β' from 0·04 radian (2·3°) at 120 Å. to 0·52 radian (30°) at 2200 Å.

Series of these measurements were also carried out using nickel-iron films from different depositions. The angle β' always increased linearly with film thickness within the limits of experimental error; but the rate of increase varied from one deposition to another, showing that factors other than film thickness affect the angular dispersion. There is, for example, some evidence that β decreases with increasing deposition rate.

Bassett *et al.*[5] have observed an increase of grain size with increasing thickness for evaporated gold films, and a similar increase is to be expected with nickel-iron. Grain size, therefore, may well be the primary factor influencing β. If it is assumed[2] that the anisotropy of the films is caused by shape anisotropy of the grains or the associated anisotropic stresses, it follows that the angular dispersion of anisotropy could arise from a scatter in the orientation of these grains. The dispersion β was obtained by allowing the magnetization to rotate from a hard direction into one or other of the easy directions, forming domains of reversed magnetization. The dispersion of any small portion of film could therefore only be detected provided that its volume V were sufficiently large to form such a domain. If its volume were smaller than this, its magnetization vector would become aligned with that of the surrounding material. If the significant volume V contains grains each of volume v, one expects β to vary statistically as $\sqrt{\frac{v}{V}}$. Accordingly, β increases with grain size and hence with film thickness.

Work is now proceeding on the effect of the deposition-rate on angular dispersion and grain size.

I wish to acknowledge helpful discussions with Mr. R. S. Webley and Dr. E. P. Wohlfarth.

SEISMOLOGY

Appearance of the *T*-Phase

Robson and Barr[1] have described the recording of bursts of seismic disturbances at Roseau on the Island of Dominica in The West Indies. The ground movement begins impulsively with a 0·3-sec. period oscillation and the whole disturbance lasts only for some 4 sec. They note that the tremors can be recorded only on the sand and gravel delta of the Roseau River, but because no local source for the tremors can be found they request the comments of other seismologists who find evidence of similar seismic phases.

In Tasmania, the University has installed a radio-telemetered seismic net[2] with a base station at Hobart and satellite stations at Moorlands, Tarraleah and Savannah. The geographical distribution of these stations is shown in Fig. 1. As was pointed out by Newstead and Watt[3] when discussing the Tasmanian net, the provision for central recording at Hobart prevents the occurrence of relative time differences

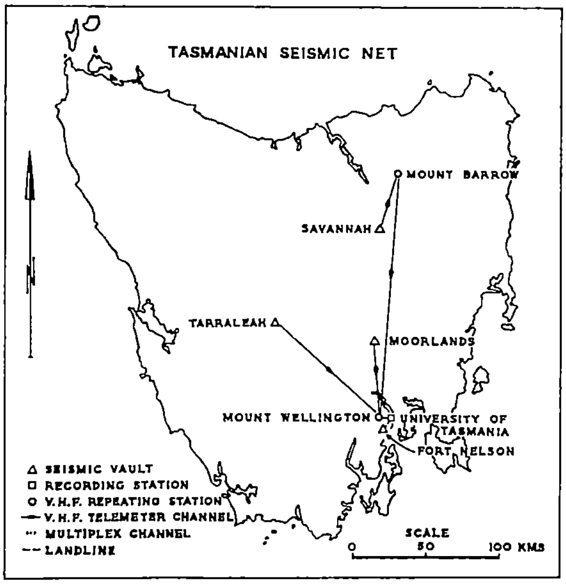

Fig. 1. Location of the stations of the University of Tasmania radio-telemetered seismic net

Table 1. DATA FOR TWO *T*-WAVES ARRIVING AT HOBART FROM MILFORD SOUND, NEW ZEALAND

Date	Epicentre	Origin time	Overall path		Water path		
			Distance (km.)	Travel time (sec.)	Distance	Travel time	Velocity
24.5.60	44·5 S. 167·5 E.	14 46 34	1,638	1,064	1,558	1050	1·48
25.5.60	44·0 S. 168·0 E.	02 37 42	1,691	1,092	1,611	1078	1·49

These seismic disturbances appear on the records as a small-amplitude, short-period tremor of limited duration. The overall epicentral distances and travel-times are given. The length of the 'Sofar' Channel which is at a water-depth of 1,500 m. is given together with the travel-time down the channel. The calculated velocity of 1·48, 1·49 is in agreement with the velocity of a compressional wave at a depth of 1,500 m.

between stations in the net. Consequently, an accurate measure of the velocity of a wave front across the continental crust of Tasmania as well as the velocity of the wave from the epicentre to Tasmania is possible.

Referring back to the appearance of the phase given by Robson and Barr[1] (see their Fig. 1), similar phases have been noted on the Tasmanian records and also on the records of other stations in eastern Australia (Doyle, H., private communication). We have identified the sources of some as due to natural earthquakes on the New Zealand side of the Tasman Sea and in other cases due to explosion of depth charges set off by naval ships. The mechanism of the transmission of the energy is as follows: From the earthquake epicentre or explosion point the energy travels as a compressional wave with a velocity of 1·47 km./sec. down the 'Sofar' Channel[4], which is a low-velocity wave-guide placed at an ocean depth of 1,500 metres. At the continental shelf conversion of energy from the channel wave phase to a *P*-phase and presumably an *S*-phase takes place. As recorded by a seismological station this *P*-phase appears to originate from a disturbance on the continental shelf.

In Table 1, the above hypothesis has been applied to two earthquakes in the Milford Sound region of New Zealand, which happens to be a prolific source of this type of wave. The channel wave can be seen to arrive 15–20 min. after the *P* wave and because of the long time-delay one may be deluded into thinking that the 'Sofar wave' or *T*-phase[5] is not connected with the initial seismic event in New Zealand. Furthermore, the wave front which forms on the continental shelf travels over the continent as a shallow *P*-wave. The late Fr. Burke-Gaffney[6] from Riverview Observatory, Sydney, examined 21 instances of this type of wave and he described them in the same terms as Robson and Barr; namely, bursts of small-amplitude high-frequency tremors. Brekhovskikh[7], in examining *T*-waves, found that the duration of the burst is dependent on the depth of water and the path-length over which the pulse travels. The constancy in appearance of the pulse as found by Robson and Barr suggests a fixed source of origin.

Byerly and Herrick[8], Dietz and Sheehy[9], and Wadate and Inouye[10] have all described the efficiency of the 'Sofar' Channel for the transmission of energy. A bathymetric map of the sea around the island of Dominica[11] shows that the 2,000-m. depth contour is very quickly reached off the coast of Roseau, thus facilitating the conversion of energy from the *T*-phase to the *P*-phase.

Shurbet[12] in 1955 examined the question of injection of energy into the 'Sofar' Channel, and he concluded that little more could be said quantitatively than to point out that the acoustical impedance across the boundary between the channel and the continent does depend on the structure of the continental shelf.

There still remains the problem of why the phase can only be positively picked up on the sediments of the delta of the Roseau River and not over the whole of Dominica Island. I would suggest that the acoustical impedance from sea water to delta sediments is very much less than from sea water to the volcanic rock of the island and as a consequence more energy is communicated to the ground in the vicinity of Roseau. Also with *P*-wave velocities as low as 0·75 km./sec. through the sediments of the delta, the amplitude of the ground movements would be enhanced, thus facilitating the recording of the phase with Willmore seismometers.

It would appear that the disturbances at Roseau are *T*-phases. These disturbances may or may not be preceded by body waves because, as pointed out by Byerly and Herrick, small earthquakes in Hawaii did not always give detectable *P* and *S* waves at California but the *T*-phase was an easily identified disturbance. If Robson and Barr could find evidence of small shocks somewhere in the Caribbean Sea[13] preceding the Roseau disturbances the problem is unambiguously resolved.

METALLURGY

Transformation of Cathodically Impregnated and Cooled Austenite

THE stabilization of austenite in two steels by hydrogen, introduced under certain special conditions, has been recently reported by us[1]. A similar but more pronounced stabilization has also been reported, by Gulyaev and Zelenova[2], for austenite monocrystals extracted by selective anodic dissolution. The stabilization can be satisfactorily explained[3], followign Cohen *et al.*[4], on the basis of the de-activation of the strain embryos in austenite by the migration and capture of hydrogen atoms, the driving force for such migration being provided by the electrolytic or pickling potential, resulting in the generation of hydrogen at pressures estimated to reach very high values. In these investigations, impregnation as well as removal of excess hydrogen by effusion, either naturally or deliberately, have been above the M_s temperatures of the steels, when they are wholly austenitic.

The effects of continuing the impregnation to temperatures well below the M_s point have now been examined, on a low-carbon, low-chromium tool steel (carbon, 1·1 per cent; chromium, 2·83 per cent) and a high-carbon, high-chromium die steel (carbon, 2·3 per cent; chromium, 13·6 per cent). These steels, with M_s temperatures of approximately 93° C. and 170° C., respectively, have been quenched from 980° C. into a 5 per cent sulphuric acid bath held at 98° C., cooled in it to room temperature (25° C.) while being cathodically impregnated and aged in air. The Vickers hardness on ageing has been determined, using, as in the previous work, a 30-kgm. load and taking all necessary precautions, the values reported being the mean of at least four perfect impressions. As a slight preparation of the surface of the specimen, after its removal from the electrolytic bath, is necessary for obtaining satisfactory hardness impressions, the first hardness measurement could be made only about 10 min. after such removal. The hardness values, which roughly indicate the extent of transformation, are shown in Fig. 1. The hardness increases appreciably within an hour of ageing, relative to the first measured value. The rise is more rapid in the initial stages and becomes virtually negligible after about 30 min. of ageing. It was unfortunate that hardness for very short ageing periods could not be recorded. However, from the recorded values, the extrapolated hardness value for an ageing period of about 1 min. appears to be substantially lower—of the order of 300–350 Vickers pyramid numbers (V.P.N.) only for the tool steel and 550 V.P.N. for the die steel. The higher value, in the latter steel, is due to cooling through nearly 80° C. in the martensite transformation-range before it is interrupted for impregnation, resulting in the retention at this stage of not more than about 25 per cent austenite, besides the high proportion of residual carbide present. This would also account for the lower over-all increase in hardness observed in this steel.

The most satisfactory explanation for these variations in hardness appears to be on the basis of the effect of pressure on phase transformation, in accordance with the le Chatelier principle. Hydrogen is generated during electrolysis at the surface of the specimen at enormous pressures. Its rapid penetration into the rifts, supposed to exist in steel[5], would further result in a considerable pressure being exerted on the microscopic portions of the austenite within the rift network. The austenite phase may therefore be expected to be considerably stabilized and the amount of martensite formed on cooling it to a fixed reference temperature to be considerably reduced, so long as electrolytic impregnation is continued and the hydrogen pressure maintained. However, as soon as the impregnation is stopped and the steel is removed from the electrolytic bath, hydrogen commences to effuse out, with release of the pressure, and the hitherto suppressed transformation may now be expected to occur in a manner roughly corresponding to the effusion of hydrogen. This would satisfactorily account for the rapid rise of hardness in the initial stages of ageing, followed by a virtually negligible increase, as most of the hydrogen effuses out within about 30 min., at room temperature, from a cathodically soaked specimen of the size employed by us.

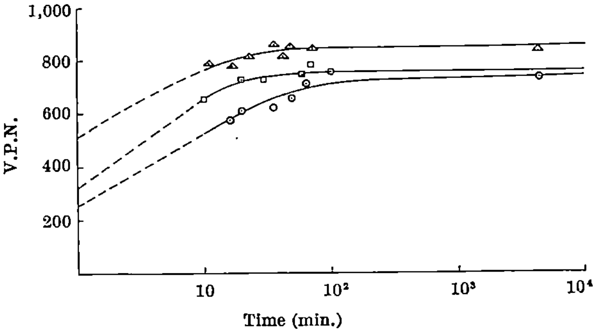

Fig. 1. Variation of hardness with time of impregnated and cooled austenite. ⊙ and □, Tool steel; △, die steel

Several authors[6–8] have examined the suppression of the austenite–martensite transformation by hydrostatic pressure. Patel and Cohen[6] estimate that the M_s point will be suppressed by about 5·7 deg. C. by a pressure of 1,000 atm. and experimentally have recorded a suppression of 8·5 deg. C. for 1,000 atm. Stregulin and Melnikov[7] have recorded a suppression of about 150 deg. C. for a pressure of about 20,000 atm. In view of the probably higher pressures prevailing during impregnation, it is quite likely that the M_s point in this investigation has been substantially depressed. Stregulin and Melnikov have also examined the subsequent isothermal transformation of austenite, the transformation of which to martensite is initially suppressed by pressure, at atmospheric as well as higher pressures, which are, however, lower than the initial suppression pressure. They indicate that in the first two or three seconds after the lowering of the pressure, the transformation proceeded very rapidly and slowed down after about ½ min. Such a very rapid initial transformation-rate may, however, be taken as improbable in our experiments, as although the effusion-rate is undoubtedly rapid, it is not so rapid as to result in the effusion of practically all the hydrogen in a few seconds. Pressure, during cathodic impregnation, is presumably exerted not only on the specimen as a whole from its exposed surface at which hydrogen is generated but also on microscopic portions of the specimen within the rift network, by hydrogen permeating into the rifts. Consequently, full release of pressure cannot be considered to follow instantaneously the removal from the electrolytic bath, unlike in the case of pressure application by classical techniques.

As the pressure of the cathodically generated hydrogen gas is dependent on the cathodic current density, it may be possible to study the austenite–martensite reaction at any value of hydrostatic pressure, merely by changing the conditions of electrolysis. The rate of release of pressure could also be probably controlled to some extent by controlling the rate of effusion of hydrogen out of the specimen—by refrigeration, for example.

Cathodic impregnation thus appears to provide a simple method of subjecting certain systems to high pressures, enabling their effects to be examined, under suitable conditions.

MINERALOGY

Tetragonal Mullite-like Phase from Co-precipitated Gels

MUCH attention has been paid to the process of formation of mullite, a refractory mineral of the composition $3Al_2O_3.2SiO_2$, through decomposition of Al–Si clay minerals and crystallization of amorphous gels. In the course of my work on allophanes and related minerals[1], a new tetragonal phase was encountered by heating the co-precipitated Al_2O_3–SiO_2 gels at the temperature-range 910°–1,100° C.

The co-precipitated gels used in the heating experiments were prepared as follows: quartz powder was fused with sodium hydroxide and dissolved in the dilute aqueous solution of sulphuric acid containing an adequate amount of alum. The concentration of SiO_2–Al_2O_3 was kept constant (1 gm./l.) for all cases. Then an excess of hexamethylenetetramine (urotropin) was added in order to attain the homogeneous precipitation of SiO_2 and Al_2O_3. The precipitate was filtered, washed with water thoroughly until either potassium, sodium or urotropin showed no trace, and then dried at room temperature.

Chemical analyses were carried out to discover what extent the ratio of Al_2O_3 to SiO_2 in the original solution would be kept in the co-precipitation, and it was found that the ratio had not been seriously affected through the co-precipitation. Eleven different gels of varying Al_2O_3–SiO_2 ratios were thus prepared (Table 1). In X-ray diffractograms the precipitate showed no diffraction lines except amorphous pattern.

Each gel was heated for 5 hr. in air at different temperatures from 800° to 1,250° C. The sample was quenched in air and examined by X-rays. The result is shown in Table 1. A mullite-like phase was detected above 910° C. in gels of composition ranging from $SiO_2 : Al_2O_3 = 10 : 90$ to $80 : 20$. This phase is converted to an ordinary mullite above 1,250° C. In the composition-range higher in Al_2O_3 than $SiO_2 : Al_2O_3 = 20 : 80$, γ-alumina was formed at about 850° C., to be converted into corundum at 1,250° C. In the composition-range higher in SiO_2 than $SiO_2 : Al_2O_3 = 70 : 30$, cristobalite was formed at 1,250° C.

Table 1. RATIO OF Al_2O_3 AND SiO_2 GELS AND PRODUCTS BY HEATING

Percentage by weight SiO_2	Al_2O_3	Molecular ratio SiO_2 : Al_2O_3	Products by heating for 5 hr. at ° C. 800	860	910	930	1,100	1,250
0	100	... : ∞	—	*A*	*A*	*A*	*Co*	*Co*

—, Gel; *A*, γ-alumina; *Mt*, mullite-like phase produced at low temperature; *Mr*, ordinary mullite; *Co*, corundum; *Cr*, cristobalite.

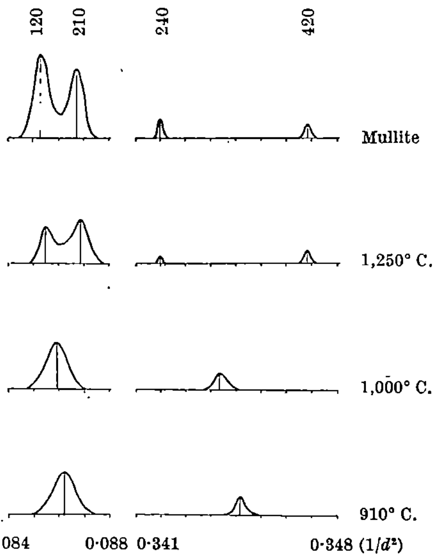

Fig. 1. X-ray diffraction pattern of products from heated Al_2O_3–SiO_2 gels and ordinary mullite

Of these eleven compositions given in Table 1, those yielding a mullite-like phase gave a sharp exothermic peak at 900°–1,000° C. in a D.T.A. curve while those yielding no mullite-like phase give no peak at the same temperature range[2]. Therefore, a close relationship between this exothermic peak in the D.T.A. curve and the appearance of the mullite-like phase might be indicated.

Further X-ray determinations were made on specimens of the composition $2SiO_2.3Al_2O_3$ heated at 910°, 1,000° and 1,250° C. with a Geiger-counter diffractometer. An arc-fusion mullite from an electrocast brick was examined for comparison. The mullite-like phase made at 910° and 1,000° C. gives generally fewer peaks than the ordinary mullite formed at 1,250° C. and arc-fusion mullite.

Table 2. LATTICE CONSTANTS AND CELL VOLUMES (v) OF PRODUCTS FROM HEATED Al_2O_3–SiO_2 GELS AND ORDINARY MULLITE

Products	a (Å.)	b (Å.)	c (Å.)	v (Å^3.)	a/b	c/b
Heated at 910° C.	7·614		2·883	167·1	1·0000	0·3786
Heated at 1,000° C.	7·625		2·882	167·6	1·0000	0·3780
Heated at 1,250° C.	7·556	7·684	2·881	167·3	0·9833	0·3749
Arc-fusion mullite	7·565	7·672	2·883	167·3	0·9861	0·3758

Especially interesting is the fact that the pairs of 120 and 210 and of 240 and 420 reflexions of ordinary mullite[3] merge each into a single peak in the mullite-like phase as shown in Fig. 1. It was found that all the peaks of the mullite-like phase can be indexed reasonably in the term of a tetragonal lattice (Table 2). When plotted in the diagram unit cell volume versus c-axis, which shows clearly the interrelations in unit-cell dimensions of various mullites and sillimanites, this tetragonal mullite-like phase falls within the range of the 'iron free synthetic mullite' designated by Agrell and Smith[4]. When plotted in the diagram *a/b* versus *c/b*, this phase falls on the linear extrapolation of the line representing the 'iron free synthetic mullite'. There is no indication that this phase has any similar evidence to sillimanite.

All the evidence appears to indicate that this new phase has a very close similarity to mullite in crystal structure.

This communication reports work from Morimoto's Laboratory of this Institute. A detailed account is now in preparation.

GEOLOGY

Two Unexplored Records of Quaternary History

DURING the last glaciation, world sea-level is generally thought to have been about 330 ft. (100 m.) below that of to-day. The rate of recovery for the last 200 ft. has been obtained from the (radiocarbon) age of peat beds and beach deposits which were covered successively by the rising sea[1]. Search for material to date the preceding 130 ft. could be made, quite reasonably, in a region of tectonic stability such as south-west England. The existing estuaries are too shallow to carry suitable material, but there are good prospects in the ground between the south coast of Ireland and the north coast of Cornwall. Here there is a hollow, the floor of which is 420 ft. below present sea-level, cut off from water of comparable depth, some 20 miles distant, by a sill the greatest depth of which is 330 ft. below present sea-level. Mitchell[2] considers that this sill and two others at a higher level in the Irish Sea are moraines, and this is supported by what is known of the composition of the sea-floor. Material from mud to stones is common. Pleistocene erratics certainly occur on the floor of the Irish Sea[3,4], and the height of the middle sill is far less than the thickness of the uncompacted materials, revealed by a seismic refraction station nearby[5].

If the southernmost sill is of Gipping age as Mitchell suggests, then it is likely that the hollow behind it was a freshwater lake during the last glaciation, during which the ice did not reach farther south than the two presumed moraines in the Irish Sea. The deepest sill was certainly land at some time for its surface is cut by two channels.

The proving of lake deposits could show that the sea had dropped below the level of the sill during the Pleistocene. The finding of a sequence of lake deposits or of peat should reveal when the sea-level rose to − 330 ft. Similar deposits in the Irish Sea could reveal when the sea-level rose to − 270 ft.

The two hollows are the sites of contemporary deposition of mud and sand, by the tidal currents, so that older materials will have been protected from erosion, at least locally, since they were covered by the sea. Search for the older materials will give a chance to assess the amount of recent deposition and therefore the importance of the supply paths that have been proposed[6].

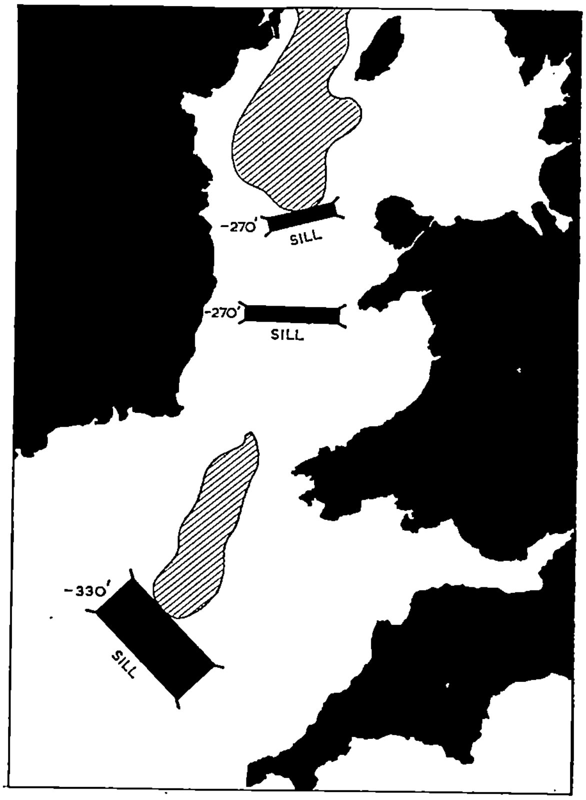

Fig. 1. The sills (? moraines) behind which freshwater lakes (diagonal shading) were probably in existence during the late Pleistocene

Examination of the northern hollow by means of the echo-sounder on R.R.S. *Discovery II* showed that there is up to 90 ft., of what experience shows can be interpreted as uncompacted material; lying partly on a rock floor. Sixty feet was proved by the same equipment in the southern hollow while a high-power, low-frequency echo-sounder, the 'Thumper', showed that the layer was underlain by other materials with a total thickness of 360 ft. (uncorrected for the velocity of sound in the material).

Further exploration is planned for the coming year, but it is anticipated that effective sampling of such sequences of deposits calls for ship-borne rotary drilling equipment of the type already used so successfully in deep water. Although such a technique is beyond the financial resources of the National Institute of Oceanography, it is hoped that the potential value of this suggested line of research will find wider support elsewhere.

CHEMISTRY

Infra-Red Spectroscopic Evidence of Four-fold Co-ordination of Titanium in Barium Orthotitanate

FOUR-FOLD co-ordination of titanium has not been reported, either in inorganic titanates or in titanium oxides. Titanium is generally present as TiO_6 octahedra, although five-fold co-ordination has been reported in a few cases[1]. However, a study of titanium-bearing garnets led me to the conclusion that titanium (Ti) replaces silicon (Si), at least in part, and thus is four-fold co-ordinated in the garnet structure[2,3].

Further spectroscopic work on synthetic compounds has now given full confirmation of this interpretation and tetrahedral co-ordination of titanium has been ascertained, not only in solid solutions of the $X_2(Si,Ti)O_4$ type, but also in a pure orthotitanate Ba_2TiO_4, in $(Ba,Sr)_2TiO_4$ solid solutions and in some glassy structures.

First, the infra-red spectra of Zn_2SiO_4, Zn_2TiO_4 and $Zn_2(Si,Ti)O_4$ compounds will be briefly discussed. Zn_2SiO_4 has been chosen as a highly discriminative case because it has tetrahedral sites only. If some silicon (1–10 mole per cent) is replaced by titanium, two possibilities only are likely to occur: (1) Titanium does enter the willemite structure and is necessarily four-fold co-ordinated. The infra-red bands related to TiO_4 tetrahedra should be characteristic both from their frequency[3] and their pattern (the infra-red pattern given by fairly dilute solid solutions has been discussed briefly in a previous paper[4]). (2) Titanium does not enter the willemite structure and thus forms a separate compound for itself, namely Zn_2TiO_4, which is an inverse spinel with titanium in six-fold co-ordination. Other possibilities are unlikely, since no intermediate ternary compound is known in the system $ZnO - SiO_2 - TiO_2$.

The observed infra-red patterns are given as block diagrams in Fig. 1. I have interpreted[5] the infra-red spectrum of Zn_2SiO_4 as follows: 1,000–850 cm.$^{-1}$, stretching modes of deformed SiO_4 tetrahedra; 460–380 cm.$^{-1}$ bending modes of deformed SiO_4 tetrahedra; 620–570 cm.$^{-1}$ stretching modes of deformed ZnO_4 tetrahedra.

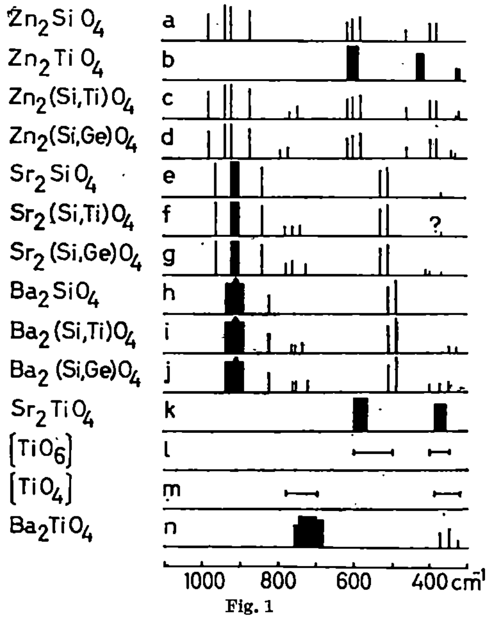

Fig. 1

No detailed interpretation is available for Zn_2TiO_4; the strong absorption centred near 590 cm.$^{-1}$ may well be due to either ZnO_4 tetrahedra or TiO_6 octahedra or both. Anyway, a detailed assignment is not needed for the present work, and the most important thing is the absence of strong bands at frequencies higher than 600 cm.$^{-1}$. This is in accordance with previous work on titanates[6], where TiO_6 octahedra have been found to absorb in the 600–500 cm.$^{-1}$ range.

The infra-red spectra of $Zn_2(Si,Ti)O_4$ samples with 1–10 moles per cent of titanium are characterized by two groups of new bands near 750 and 320 cm.$^{-1}$ (Fig. 1*c*), the intensities of which depend on the amount of titanium introduced; it is clearly impossible to attribute them to Zn_2TiO_4; moreover, their assignment to TiO_6 octahedra is inconsistent with the fairly high values 765 and 747 cm.$^{-1}$; as a matter of fact, this is within the absorption-range of GeO_4 tetrahedra as observed in orthogermanates (Tarte, T., unpublished results). On the other hand, GeO_4 tetrahedra in the $Zn_2(Si,Ge)O_4$ solid solutions gave a very similar infra-red pattern (Fig. 1*d*). This striking similarity is perhaps the most important reason for believing that titanium is also present in solid solution as TiO_4 tetrahedra.

If taken separately, each of these facts may be given several interpretations, but if considered simultaneously, they fully demonstrate that titanium has entered the willemite structure and is four-fold co-ordinated: the two groups of bands near 750 and 320 cm.$^{-1}$ are assigned to the stretching and bending modes respectively of slightly distorted TiO_4 tetrahedra.

Quite similar infra-red patterns have also been observed for other solid solutions such as $Sr_2(Si,Ge)O_4$ and $Sr_2(Si,Ti)O_4$, or $Ba_2(Si,Ge)O_4$ and $Ba_2(Si,Ti)O_4$ (Fig. 1, *e–j*), and this is again good evidence that a moderate amount of titanium may be introduced on the tetrahedral sites of these structures.

Let us now consider the case of pure Sr_2TiO_4 and Ba_2TiO_4. It turns out that these substances give quite different infra-red spectra.

In Sr_2TiO_4, titanium is six-fold co-ordinated[7] and the observed infra-red spectrum (Fig. 1*k*) agrees with the general pattern of (TiO_6) octahedra (Fig. 1*l*) as observed in a series of metatitanates[6]. In Ba_2TiO_4, the detailed structure of which is still unknown, the strongest absorption is observed near 720 cm.$^{-1}$, a rather high value if compared with Sr_2TiO_4 or other structures with titanium in six-fold co-ordination. The infra-red spectrum of Ba_2TiO_4, however, agrees nicely with the characteristic frequencies of TiO_4 tetrahedra (Fig. 1, *m* and *n*). The same pattern is observed for $(Ba,Sr)_2TiO_4$ solid solutions (containing up to 10 moles per cent of Sr), which have essentially the same structure as Ba_2TiO_4. Further proof of the occurrence of TiO_4 tetrahedra has been given by the study of the composition $Ba_2(Ti_{0\cdot95}Si_{0\cdot05})O_4$. There is full spectroscopic evidence that silicon is present in solid solution as SiO_4 tetrahedra, thus confirming the occurrence of tetrahedral sites in the Ba_2TiO_4 structure. Tetrahedral co-ordination of titanium in Ba_2TiO_4 is thus definitely established. This is the first reported example of such a co-ordination in a titanate, but this result is in accordance with the suggested analogy of structure between Ba_2SiO_4 and Ba_2TiO_4 (ref. 8).

It should be pointed out that the absorption of TiO_4 tetrahedra in the 700–800 cm.$^{-1}$-region is fairly strong and allows an easy discrimination between TiO_4 tetrahedra and TiO_6 octahedra. The method may be applied even to glassy structures, where I was able to detect spectroscopically both tetrahedral and octahedral co-ordination of titanium[9].

Selectivity of Palladium Catalysts for the Oxidation of Carbon Monoxide in the Presence of Hydrogen

IT is known that a palladium catalyst used for the removal of traces of oxygen from hydrogen at room temperature is readily poisoned by carbon monoxide[1,2].

To remove oxygen or carbon monoxide from hydrogen containing both gases it is necessary, therefore, to work at higher temperatures. Catalysts recommended for effecting a selective oxidation of a few per cent of carbon monoxide in the presence of an excess of hydrogen are the metals of the eighth group of the Periodic System, especially platinum, rhodium and ruthenium[3].

These catalysts work selectively only between about 120° and 160° C.: below 120° C. poisoning occurs, above 160° C. the selectivity becomes lost.

W. J. Hanssen[4], when determining traces of carbon monoxide in the 5–200 p.p.m. range, applied platinum gauze at somewhat higher temperatures.

We carried out experiments with hydrogen gas containing only traces of carbon monoxide (50 p.p.m.) and found that in this case selective oxidation occurs already at room temperature. The results are given in Table 1.

Table 1. SELECTIVE OXIDATION OF CARBON MONOXIDE IN THE PRESENCE OF HYDROGEN ON 0·5 PER CENT PALLADIUM ON ALUMINA CATALYST (TOTAL PRESSURE 1 ATM., 50 P.P.M. CARBON MONOXIDE AND 0·2 PER CENT OXYGEN

Temperature (° C.)	Space velocity (h^{-1})	Conversion of carbon monoxide (per cent)
20	3,000	95
20	1,000	92
30	1,000	92
50	1,000	95
75	1,000	95

Throughout the period of investigation (several days) no indication of loss of activity was noted. The carbon monoxide was shown to have been oxidized to carbon dioxide and the oxygen content had been brought down to less than 0·1 p.p.m. An increase of the carbon monoxide concentration to 200 p.p.m. resulted in total poisoning of the catalyst. The poisoning was reversible.

The reactor used worked practically isothermally. The analysis was carried out with Hanssen's method (mentioned above) adapted to our lower concentration-range.

It can be concluded that removal of traces of carbon monoxide from hydrogen (necessary in some catalytic hydrogenation reactions) can be carried out already at room temperature.

pH of Soap Solutions

THE specific conductivity and *p*H of sodium laurate solutions have been measured at several temperatures within a concentration-range of 10^{-1} *M*–3 × 10^{-5} *M*. The apparatus used was a modification of that used by Franks[1] for the chromatography of long-chain fatty acids. It enabled a concentrated (10^{-1} *M*) soap solution to be diluted continuously with rigorous exclusion of carbon dioxide at all stages, beginning with preparation of the soap.

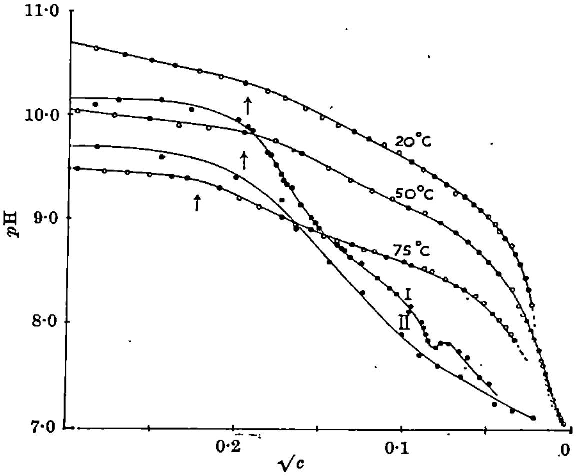

Fig. 1. *p*H of sodium laurate solutions. ○, This work; I, ref. 2 (20°); II, ref. 3 (25°)

The results are best presented graphically, and Fig. 1 shows the *p*H of sodium laurate solutions as a function of $\sqrt{c}$ at 20°, 50° and 75° C. The results of Ekwall[2] and McBain[3] are included for comparison. The present *p*H values are consistently higher than those of earlier workers and show very little scatter. The critical micelle concentration at each temperature is indicated by an arrow. Although the critical micelle concentration at 20° seems rather high compared with other published results, this could well be due to the total exclusion of carbon dioxide. Our value of 3·4 × 10^{-2} *M* is in excellent agreement with that obtained recently from e.m.f. measurements with membrane electrodes[4].

Fig. 2 shows the *p*H of a sodium laurate solution at 50° as a function of log *c* at extreme dilutions. At soap concentrations less than 10^{-4} *M* a linear relationship between *p*H and log *c* is obtained. The slope is in good agreement with the Debye–Hückel limiting law for uni-univalent electrolytes, and the soap behaves as a salt of a strong base and a weak acid. However, at concentrations greater than 10^{-4} *M*, marked deviations from ideal behaviour occur, possibly due to pre-association equilibria. The

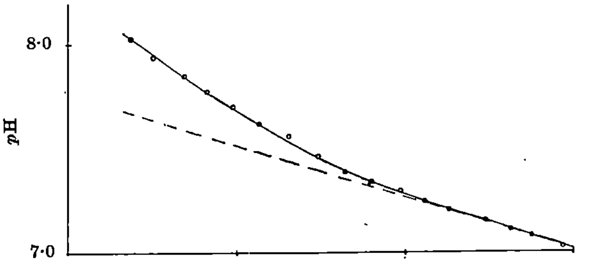

Fig. 2. pH of sodium laurate solutions at 50° C. over the low range of concentration. The dashed line represents the Debye–Hückel slope for a uni-univalent electrolyte

possibility of some form of pre-association below the critical micelle concentration has been suggested to account for the conductivity of sodium dodecyl sulphate[5], but the importance of such an effect has recently been discounted[6].

Theoretical Expression for Solubility Product

WHILE considering some questions on ionic interactions in a medium, I noticed a communication under this heading which includes an erroneous assumption[1].

Stating the potential energy of a 'system' of oppositely charged ions as:

$$U = \left\{ -\frac{(z_+\varepsilon)(z_-\varepsilon)}{R_0}\left(1 - \frac{1}{n}\right) - \frac{\alpha_a(z_+\varepsilon)^2 + \alpha_c(z_-\varepsilon)^2}{2R_0{}^4} \right\} \quad (1)$$

Krishnamurti derived an equation of the solubility product (equation 6) as:

$$-\log_e S_p = \left\{ \frac{\alpha_a z_+{}^2\varepsilon^2 + \alpha_c z_-{}^2\varepsilon^2}{2R_0{}^4} \right\} \Big/ RT + a \quad (2)$$

assuming that for very small values of R_0 the first term in (1), namely $\frac{-\varepsilon^2}{R_0}\left(1 - \frac{1}{n}\right)$, can be neglected in comparison with the second term representing the mutual ion-dipole interaction. (In equation 1, n is a constant which is approximately 9, α_a and α_c are polarizabilities of anion and cation respectively, z_+ and z_- are valencies of anion and cation, ε is the electronic charge and R_0 the equilibrium distance between the centres of the two ions.)

The assumption that, for very small values of R_0, the first term in (1) can be neglected in comparison with the second term is not correct. As the distance of closest approach of two ions can never be less than 10^{-8} cm. (except in the case of nuclear events), it can be seen that the first term can never be less than the second term. With α of the order of 10^{-24} cm.^{3}, $e = 4{\cdot}803 \times 10^{-10}$ E.S.U., and with minimum value of R_0 is of the order of 10^{-8} cm., and with n and 9 it is seen that the first term is always greater than the second term at least by a factor of 10 for ions of different values of Z as 1, 2, 3, etc. Hence the first term can never be neglected in comparison with the second term. The first term, representing energy due to Coulomb interaction, is of course more important than that of the attraction resulting from the polarization of each ion in the field of the other as represented by the second term.

At constant temperature and with R_0 constant for compounds of similar constitution, a plot of $\log_{10} S_p$ against $\alpha_a z_+{}^2 + \alpha_c z_-{}^2$, Fig. 1 of Krishnamurti's communication, gave a straight-line graph, which led him to think that the derivation of equation 2 above was correct. But it should be noted that with n and R_0 constant (which point is also subject to question) the first term $\frac{z_+z_-\varepsilon^2}{R_0}\left(1 - \frac{1}{n}\right)$ itself becomes constant and thus equation 7 of that communication becomes:

$$-\log_{10} S_p = K(\alpha_a z_+{}^2 + \alpha_c z_-{}^2) + \lambda$$

where λ is another constant in which the contribution of the first term is included and thus a plot of $\log_{10} S_p$ against $\alpha_a z_+{}^2 + \alpha_c z_-{}^2$ would also lead to a straight-line graph. Thus a straight-line graph for $\log_{10} S_p$ against $\alpha_a z_+{}^2 + \alpha_c z_-{}^2$ does not justify the neglect of the first term, which, as I have explained, is more important than the second term.

I also wish to point out a discrepancy in equation 6 of Krishnamurti's communication (equation 2 here). By considering the interaction energy of two ions only, as in equation 1 here and not for all ions in a mole, Krishnamurti has arrived at equation 6 assuming his equation 3; in both equations RT there should be $\varkappa T$, where $\varkappa$ is Boltzmann's constant.

B. N. BHAR

Physics Department,
College of Science,
University of Baghdad.

[1] Krishnamurti, K., *Nature*, **182**, 1227 (1958).

WHEN an ionizable compound BA is dispersed in water to form a saturated solution, equilibrium is attained with the rate at which the ions detach themselves from unit area of the surface of the solid particles (crystals) and go into solution, and is equal to the rate at which the ions recombine to form the molecules which are deposited on the same area of the surface. The rate of recombination of the oppositely charged ions $B^{\cdot}$ and A' to form BA, being deposited on unit area of the solid surface, is given by the expression: $k_1 n_{B^{\cdot}} n_{A'} . \exp(-E_1/RT)$, where $n_{B^{\cdot}}$ and $n_{A'}$ are the numbers of cations $B^{\cdot}$ and anions A' per unit volume of the solution; k_1 is a constant and E_1 is the energy per gm.-mole which the ions should possess to escape from the ionic atmosphere and from the solvation layers around the ions. This energy term was neglected in the earlier communication[1] and it should be correctly expressed as:

$$E_1 = N_0 \left\{ \frac{(z_+\ \varepsilon).(z_-\ \varepsilon)}{DR_1} + c\left(\frac{5}{9} \cdot \frac{A}{R_2^4} + \frac{7}{9} \cdot \frac{B}{R_2^2}\right) \right\} \quad (1)$$

where the first term represents the Coulomb attraction and the second[2] the energy of interaction between an ion of charge $z\varepsilon$ and c equidistant molecules of

Table 1

water at a distance R_2 from its centre ; $A = \frac{1}{2}\alpha(z\varepsilon)^2$; $B = z\varepsilon\mu$. N_0 is the Avogadro number ; z_+ and z_- denote the valencies of the positive and negative ions ; ε is the electronic charge, α the polarizability and μ the dipole moment of the water molecules; R_1 is the radius of the ionic atmosphere, and D is the dielectric constant of the medium.

The rate of re-dispersion of these ions from unit area of the surface of the solid BA in contact with the saturated solution is $k_2.n'.\exp(-E_2/RT)$, where n' is the number of pairs of ions ($B^{\cdot}$ and A') per unit area of the surface, and this re-dispersion of ions will take place when they possess energies exceeding E_2, which is the energy due to the attraction caused by Coulomb forces and the mutual polarization of ions:

$$E_2 = N_0\left\{\frac{A_0(z_+\ \varepsilon)\ (z_-\ \varepsilon)}{R_3}\left(1 - \frac{1}{n}\right) + \frac{\alpha_a(z_+\ \varepsilon)^2 + \alpha_c(z_-\ \varepsilon)^2}{2R_3^4}\right\} \quad (2)$$

where A_0 is the Madelung constant, n occurs in Born's repulsion energy term, α_c and α_a are the polarizabilities of the ions, R_3 the interionic distance in crystals. In addition to these interactions it may sometimes be necessary to consider the dispersion forces between the ions, which may be of significance at close distances of approach of the ions characterized by higher polarizabilities. At equilibrium:

$$K_1'(N_B{\cdot}N_{A'}).\exp\left[-N_0\left\{\frac{(z_+\ \varepsilon).(z_-\ \varepsilon)}{DR_1} + c\left(\frac{5}{9}\cdot\frac{A}{R_2^4} + \frac{7}{9}\cdot\frac{B}{R_2^2}\right)\right\}\right]\Big/RT$$

$$= K_2'N'.\exp\left[-N_0\left\{\frac{A_0(z_+\ \varepsilon).(z_-\ \varepsilon)}{R_3}\left(1 - \frac{1}{n}\right) + \left\{\frac{\alpha_a(z_+\ \varepsilon)^2 + \alpha_c(z_-\ \varepsilon)^2}{2R_3^4}\right\}\right]\Big/RT \quad (3)$$

It was stated in the previous communication[1] that for small values of R_3 the term $\left(\frac{(z_+\ \varepsilon)(z_-\ \varepsilon)}{R_3}\right)$ can be neglected in comparison with the second term representing the mutual ion-dipole interactions. As pointed out by Dr. B. N. Bhar, this is not correct for the commonly accepted values of inter-ionic distances. This error did not, however, invalidate the main expression (5) or the approximate expression (6) given earlier[1]. This term may be omitted from the final expression when its numerical value is of the same order of magnitude as the term:

$$\left\{\frac{(z_+\ \varepsilon)(z_-\ \varepsilon)}{DR_1} + c\left(\frac{5}{9}\cdot\frac{A}{R_2^4} + \frac{7}{9}\cdot\frac{B}{R_2^2}\right)\right\}$$

occurring on the left side of equation (3). Then we may write (3) in a simpler form:

$$-\log_e S_p = -\log_e(N_B{\cdot}N_{A'}) = N_0\left\{\frac{\alpha_a(z_+\ \varepsilon)^2 + \alpha_c(z_-\ \varepsilon)^2}{2R_3^4}\right\}\Big/RT + a \quad (4)$$

where $N_{B^{\cdot}}$,$N_{A'}$ relate to gm.ions and a is a constant. This is almost the same expression which was obtained previously[1]. Its validity is revealed by results given in Table 1. The agreement between the experimental values of $-\log_e S_p$ and those calculated from the expression (4) using the values of R_3 given in column 4 is quite good. If we use instead the inter-ionic distances (R_t) obtained from the usually accepted values of ionic radii in this expression, we have to multiply it by a factor $\gamma = \left(\frac{R_t}{R_3}\right)^4$. There is a general proportionality between γ and the extent of covalent bonding in the corresponding halides. Thus, expression (4) should be written in a more general form as follows:

$$-\log_e S_p = \beta N_0\left\{\frac{\alpha_a(z_+\ \varepsilon)^2 + \alpha_c(z_-\ \varepsilon)^2}{2R_3^4}\right\}\Big/RT + a \quad (5)$$

where β corrects for the covalent contribution to the bond between the ions in the crystal, which causes a decrease in the solubility of the salt. In fact, copper, silver and mercury show considerable tendency to form covalent compounds, and their halides (except fluorides) show very low solubilities.

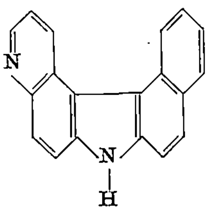
BIOCHEMISTRY

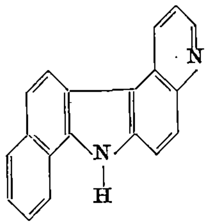
A New Family of Potent Carcinogens : Benzopyridocarbazoles

Although the introduction of heterocyclic nitrogen atoms in the molecules of polycyclic compounds sometimes decreases carcinogenic activity (for example, the inactive pyrenoline as compared with 3,4-dibenzopyrene[1]), there are many instances in which the carcinogenic potency is thereby maintained or even enhanced. Such is the case with the angular benzacridines[2], some of which are more active than the corresponding 1,2-benzanthracenes in respect of induction of skin epitheliomas and sarcomas, and with the inactive pentacene, in the molecule of which the introduction of two nuclear nitrogen atoms leads to the sarcoma-producing dinaphthazine[3]. In view of the already established carcinogenic activity of the angular dibenzocarbazoles[4], it was interesting to examine the biological properties of the recently synthesized aza derivatives[5].

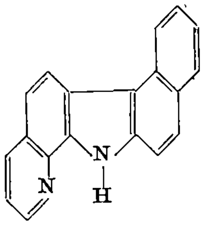
A first series of experiments concerned four such compounds: 3,4-benzopyrido(3′,2′:5,6)carbazole (I), 1,2-benzopyrido(3′,2′:5,6)carbazole (II), 5,6-benzopyrido(2′,3′:1,2)carbazole (III), and 5,6-benzopyrido(3′,2′:1,2)carbazole (IV). The first is an aza derivative of 3,4:5,6-dibenzocarbazole, and the other three are aza derivatives of 1,2:5,6-dibenzocarbazole.



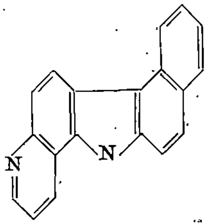
(I)



(II)



(III)



(IV)

Using male and female mice aged 4–6 months and belonging to strain XVII *nc/Z* (Radium Institute), the substances were injected subcutaneously in the flank (3 injections of 0·6 mgm. of the substance in 0·2 c.c. olive oil, with an interval of one month between injections). The results are recorded in Table 1; no hepatic lesions were observed in any of the mice.

Table 1

Substance	No. of animals	No. of sarcomas	Average latency (days)	Sarcoma index (after Iball)
I	14 7♂	1	106	13
	7♀	0	—	0
II	14 7♂	2	273	10
	7♀	1	200	7
III	16 8♂	8	157	64
	8♀	1	178	7
IV	15 7♂	7	100	100
	8♀	6	118	73

From these results, it can be seen that the group of aza derivatives includes carcinogens with various degrees of activity, some of them being extremely potent. Compound (IV), for example, ranks among the most powerful sarcomagenic substances known, with both a high proportion of tumours and a strikingly short induction period. A shift in the position of the pyridinic nitrogen atom can diminish this activity either slightly (compound III), or considerably (compound II). Hence, it is clear that, as in the benzacridine series, biological activity is to a large degree dependent on the position occupied by the pyridinic nitrogen atom; and this opens the field for a broad investigation into relationships between structure and activity in this new chemical series, an investigation which is now being pursued here.

Amino-Acid Activation in Tissues of Early Embryos

The work of Hoagland, Zamecnik and many others[1–4] has now clearly established that activation of the carboxyl groups of amino-acids occurs as one of the initial steps before they are incorporated into proteins during protein synthesis. The activation reaction was demonstrated by these workers, in protein-synthesizing components of a variety of mammalian tissues. Recently amino-acid activation has also been shown to occur in sea-urchin eggs; but I have seen no reports to date of any investigations on tissues of developing embryos.

The work to be reported briefly here shows that amino-acid activation can be detected in embryos of the clawed toad, *Xenopus laevis*, and it also deals with the occurrence of leucine-activation in tissues of both *Xenopus* and chick embryos. Fuller details of the work on *Xenopus* are in process of publication[6]. Amino-acid activation has been measured as an increased rate of exchange of phosphorus-32 between radioactive pyrophosphate (PP) and adenosine triphosphate (ATP) in the presence of added amino-acid, as compared with the exchange-rate without added amino-acid. The principles and details of the method have already been described[4–6]. Supernatants from tissues homogenized in ice-cold 0·05 *M* potassium chloride at *p*H 7·5 and centrifuged in the cold at 20,000*g* have been used as sources of enzyme.

Table 1 gives the results of testing supernatants from hatching-stage *Xenopus* embryos with a number of different amino-acids. It is apparent that all these show activation, that is, the PP–ATP exchange-rates are higher than when no amino-acid is added (controls). The most marked activation is shown for tryptophan, tyrosine and leucine. In later work[6] on the distribution of leucine-activation in dorsal and

Table 1. Enhancement of PP–ATP Exchange by Various Amino-acids, in Extracts of Hatching-stage *Xenopus* Embryos

Amino-acid added (2·0 μmoles)	% PP–ATP exchange*
None (controls)	0·751
Serine	3·265
Threonine	3·478
Glutamine	3·736
*Iso*leucine	4·276
Tryptophan	5·669
Tyrosine	4·341
Leucine	6·171

$$* \ \%\text{Exchange} = \frac{\text{specific activity of ATP (counts/min. } \mu\text{mole)}}{\tfrac{1}{2}\text{ specific activity of PP (counts/min. } \mu\text{mole)}} \times 100$$

Table 2. LEUCINE-ACTIVATION IN DORSAL TISSUES OF *Xenopus* EMBRYOS, AT LATE NEURULA TO EARLY TAIL-BUD STAGES
Activation expressed as percentage increases in PP–ATP exchange-rate in the presence of 2·0 μmoles of L-leucine, per 10 μgm. total nitrogen in supernatant sample. Means and standard errors of five experiment

	% increase in PP–ATP exchange
Somite tissue	34·3 ± 9·2
Nervous tissue	25·7 ± 7·8

ventral regions of embryos, it was found that dorsal halves of late neurula and tail-bud stages had a particularly high leucine-activating activity, and that when these dorsal halves were divided into somite and central nervous tissue portions, the highest leucine-activation was shown in the somite tissue (Table 2: the activation figures are here expressed as percentages and related to total nitrogen in the enzyme samples). The difference between somite and nervous tissue was highly significant ($t = 4{\cdot}9954$, $P < 0{\cdot}01$ for the paired differences between values for somite and nervous tissue in five experiments).

The same method has been used for measuring leucine-activation in somite and central nervous tissues of 48-hour chick embryos (stage 11–13 of Hamburger and Hamilton's series[7]). The only methodological difference was that the volumes of all reagents in the incubation mixture were reduced to a quarter of those used for the *Xenopus* extracts, since the total bulk of chick tissues available was very much smaller (the total nitrogen in chick supernatants was only one-tenth of that in *Xenopus* supernatants). The results with chick tissues were far more striking than those with *Xenopus*, and increases of PP–ATP exchange of more than 100 per cent were obtained (Table 3). Again, the leucine-activation in somite tissue was higher than in central nervous tissue ($t = 8{\cdot}2975$, $P < 0{\cdot}01$, for the paired differences between values for somite and nervous tissue in five experiments).

Table 3. LEUCINE ACTIVATION IN TISSUES OF 48-HR. CHICK EMBRYOS
Percentage increases in PP–ATP exchange-rate in the presence of 0·5 μmole of L-leucine per μgm. total nitrogen in supernatant sample. Means and standard errors of five experiments

	% increase in PP–ATP exchange
Somite tissue	181·89 ± 29·83
Central nervous tissue	100·64 ± 29·45

The specially high leucine-activation in somite tissue extracts of both *Xenopus* and chick embryos suggests that more leucine is being taken up into proteins of somite cells at this particular stage of development than elsewhere in the embryo. As we are dealing, in both types of embryo, with stages during which the somites are segmenting, it is of interest to note that, in chick embryos, somite segmentation can be blocked by analogues of leucine[8,9], or, conversely, speeded up by adding normal leucine to the culture medium[10]. It is not at all clear what role leucine could have in controlling the process of somite segmentation. One might, however, speculate that somitic myoblasts are prime users of this amino-acid, at least during the time that they are synthesizing myosin, for this protein contains a high proportion of leucine[11]. Holtzer, Marshall and Finck[12] have detected myosin in chick skeletal myoblasts at stages only slightly later than those used here, that is, about 56 hr. incubation (stage 16, 17). So it is reasonable to suggest that at stages 11–13 leucine could already be being taken up into myosin precursors. Autoradiographical work is needed to elucidate this point, and some has already been started by me.

Returning to the evidence (Table 1) that in late *Xenopus* embryos activation of a number of amino-acids can be demonstrated, this is of general interest because one should certainly expect embryonic tissues which are differentiating to be carrying out very active protein synthesis. It would seem that we have here a promising and wide-open field for further study.

Changes in the Pentose–Nucleic Acid Content of Sub-cellular Fractions of the Brain of the Rat during 'Metrazol' Convulsions

CHANGES in the content of pentose–nucleic acid in the nerve cells during increased functional activity have been reported by several workers. A depletion of pentose–nucleoprotein in the stimulated anterior horn cells has been observed by Holger Hyden[1]. Similarly, a decrease in the concentration of pentose–nucleic acid, together with an alteration of molar base ratios, has been reported in the stimulated area of the brain cortex in cats[2]. A consistent decrease in pentose–nucleic acid and protein content of the brain of the rat during 'Metrazol' convulsions has been observed and reported elsewhere[3].

In the present communication the changes in pentose–nucleic acid of various sub-cellular fractions of brain of the rat during convulsions are presented.

Convulsions were induced by injecting 'Metrazol' into albino rats[4], keeping litter-mates as controls. The animals were decapitated in the tonic phase of convulsions and the heads frozen by dropping them in liquid air. The frozen brains from two animals were pooled, quickly weighed and the nuclei separated by the method of Alfrey, Osawa and Mirsky[5]. Microsomal and *p*H 5 pentose-nucleic acid fractions were separated by the methods of Osawa, Takata and Hotta[6] and of Schweet, Lamform and Allen[7] respectively. From the sucrose nuclei, the *p*H 7·1 soluble pentose–nucleic acid fraction and the nucleolar pentose–nucleic acid fraction were separated by the method described by Alfrey and Mirsky[8]. From the fractions thus obtained pentose-nucleic acid was extracted and estimated according to the micro method of Scott, Fraccastoro and Taft[9].

Table 1 summarizes the net change in each of the sub-cellular fractions. It is apparent that the depletion in the content of pentose–nucleic acid during convulsions is primarily confined to the nuclear fractions. Ruth S. Geiger[10] has observed in histological studies that an extrusion of the nucleolar material occurred

Table 1. Pentose-Nucleic Acid (PNA) Content of Various Subcellular Fractions in Normal Rat Brain and After 'Metrazol' Convulsions

PNA fraction		Control	'Metrazol' convulsive	Percentage of change
Nuclear	Soluble	6·4 ± 0·73 (12)	4·8 ± 1·04 (12)	−25
	Nucleolar	27·4 ± 4·4 (12)	20·6 ± 4·5 (12)	−24
Cytoplasmic	Soluble	22·5 ± 3·6 (12)	21·8 ± 5·0 (12)	− 3·1
	Microsomal	52·6 ± 5·2 (10)	49·4 ± 5·3 (12)	− 6
Total	Nuclear	33·8 ± 4·4 (12)	25·5 ± 4·0 (12)	−24·5
	Cytoplasmic (excluding mitochondrial)	75·6 ± 9·6 (10)	71·3 ± 6·3 (12)	− 5·6
Total (cytoplasmic + nuclear)		107·8 ± 15·8 (10)	96·8 ± 13·6 (12)	−10·2

The figures in parenthesis indicate the number of animals used. The brains of two animals were pooled together for obtaining a single observation. Values are expressed in μgm./100 mgm. wet weight of tissue. Against each value, the mean standard error is given.

in neurons in tissue culture when subjected to electrical stimulation or 'Metrazol' action.

This fall in nuclear pentose-nucleic acid may be due to an enhanced activity of ribonuclease in the nucleus as a result of convulsive activity or it might indicate an increased passage of pentose-nucleic acid from the nucleus to the extra nuclear compartments in convulsive or electrically stimulated states. Relationship of these changes with the functional activity of the neurons is not yet defined.

Rapid Infra-Red Determination of Acetone in the Blood and the Exhaled Air of Diabetic Patients

There has long been a need for a rapid method for the quantitative determination of acetone in the blood and in the exhaled breath of the patient with diabetes mellitus. Since these concentrations are a direct reflexion of the diabetic state, precise acetone measurements would provide the physician with more accurate data with which to evaluate his diabetic patient. To be clinically practical, this analytical method should be specific, sensitive and rapid. An extension of an infra-red method previously reported[1] provides the basis for this preliminary report on the analysis of actone in blood and in the expired air.

To determine the acetone in blood, a 10-ml. oxalated sample is pipetted into a 40-ml. glass centrifuge tube fitted with a ground-glass stopper. 15 ml. of carbon disulphide is added, and the tube gently shaken for 10 min. on an automatic shaker. The tube is then centrifuged in a refrigerated centrifuge for 5 min. at 1,500*g*. The solvent layer is transferred to a 15-mm. infra-red sample cell and the absorbance at 8·25μ measured. To compensate for solvent absorption a matching cell filled with carbon disulphide is placed in the reference beam of the spectrometer. The minimal amount of acetone detectable in blood by this solvent extraction technique is 1·5 mgm. per cent (15 p.p.m.). The standard deviation in the analysis of a sample of blood containing 13·7 mgm. per cent of acetone is 0·76 mgm. per cent, while that of a 61·4 mgm. per cent acetone in a blood standard is 2·2 mgm. per cent.

Expired air for acetone analysis is collected by having the diabetic patient slowly exhale into a 10-l. 'Saran' bag. This expired air is allowed to flow into an evacuated gas cell of path 40-m. long mounted on a Perkin–Elmer model 221 infra-red spectrophotometer. The absorbance at 8·25μ is measured to determine the concentration of acetone. The minimal amount of the compound detectable is 10 μgm./l. of expired air. The standard deviation in an air sample containing 600 μgm./l. is 31 μgm./l.

The infra-red analysis of blood acetone has proved to be clinically practical. It provides a precise measurement of acetone in the case of diabetic acidosis, obviating the use of the 'Acetest' method for estimating the degree of ketonæmia by serial serum dilutions. Because of the sensitivity of the method, blood acetone may be determined when present in concentrations below the sensitivity of the 'Acetest' tablet.

The determination of acetone concentration in the expired air by this method is most promising. It has been possible to detect acetone in the breath of patients with blood concentrations less than 1·5 mgm. per cent, and in the acidotic diabetic it has proved to be the most rapid means of establishing the exact degree of acidosis. As the concentration of air in the alveoli parallels the concentration in the blood, the effect of treatment of the diabetic in acidosis is easily ascertained.

Influence of Scurvy and Lathyrism (Odoratism) on Hydroxyproline Excretion

Since nearly all the hydroxyproline in the body is found in collagen, it has been suggested[1–3] that abnormal amounts of hydroxyproline may be excreted in conditions which alter the metabolism of collagen. The availability of a specific and relatively simple method for analysing hydroxyproline in urine[4] encouraged us to measure hydroxyproline excretion in scurvy and lathyrism (odoratism), two experimental conditions known to affect collagen.

To study the effect of scurvy, male guinea pigs (Hartley) were fed a scorbutogenic diet[5], and the urinary excretion of hydroxyproline was measured[4] daily for 24 days. Five test animals received the scorbutogenic diet alone, and 5 control animals received the diet and an oral supplement of 1 mgm. of ascorbic acid per day. The hydroxyproline excretion was essentially the same in both groups for the first 19 days on the diet, but from the 20th to the 24th day the animals not receiving ascorbic acid excreted significantly less hydroxyproline (0·45 ± 0·05 mgm. versus 1·12 ± 0·10 mgm. per day). On the 21st day the ascorbic acid-deficient animals showed histological evidence of scurvy[6]. In other experiments guinea pigs were placed on the scorbutogenic diet and divided into three groups : group 1 received 1 mgm. ascorbic acid per day throughout the course of the experiment, group 2 received no ascorbic acid, and group 3 received 10 mgm. of ascorbic acid on the 21st day of the experiment. Urine was collected from the 21st to the 22nd day. As shown in Table 1, urinary hydroxyproline excretions were depressed in animals on the scorbutogenic diet but were rapidly restored to normal by administration of ascorbic acid. On the 22nd day the animals in group 1 weighed 20 per cent less than those in group 2. To demonstrate that the decrease in hydroxyproline excretion was not the result of loss of weight, 15 guinea pigs were starved for 2 days. Their body-weights fell from a mean of 195 gm. to a mean of 168 gm., but their urinary hydroxyproline-levels were unchanged.

Table 1. DECREASE OF HYDROXYPROLINE EXCRETION IN SCURVY AND INCREASE OF HYDROXYPROLINE EXCRETION IN LATHYRISM

Animals	Number	Diet*	Supplement	Hydroxyproline per 24 hr. mgm. ± *S.E.*
Guinea pigs (Group 1)	10	scorbutogenic	1 mgm. ascorbic acid/day	1·13† ± 0·15
(Group 2)	31	,,	none	0·57† ± 0·08

* Both diets hydroxyproline-free.

† Hydroxyproline excretions for the twenty-first day of the experiment.

‡ Hydroxyproline excretions for the fifty-fifth day of the experiment.

§ BAPN, β-aminopropionitrile, supplied by Abbott Laboratories.

To study the effect of a lathyrogenic agent on hydroxyproline excretion, weanling rats and adult rats were placed on a low protein diet[7], and half the animals from each group were injected with 160 mgm. β-aminopropionitrile (BAPN) per day. No difference in urinary hydroxyproline excretion between control and injected animals was observed on the 4th and 20th days of treatment, and there was no gross evidence of lathyrism. By the 55th day, the BAPN-treated animals excreted two to three times as much hydroxyproline as controls (Table 1) and all the animals had marked scoliosis. More than 90 per cent of the hydroxyproline in the urine from both control and experimental animals was dialysable.

Several other conditions which might change hydroxyproline excretion were also investigated. Young guinea pigs (11–20 days) were found to excrete significantly more hydroxyproline than adult guinea pigs (2 years old). The young animals, weighing 100–180 gm., excreted an average of 1·84 ± 0·15 mgm. hydroxyproline per 24 hr. as compared with an average of 1·22 ± 0·20 mgm. per 24 hr. excreted by 2 kgm. adult animals. Comparable age differences have been reported previously for humans[1] and rats[8]. Preliminary experiments have confirmed the earlier report[9] that urinary hydroxyproline is not altered by parturition. In addition, our results indicate that urinary hydroxyproline-levels are not altered by parathyroidectomy or the injection of papain or carrageenan.

The results obtained here indicate that the extensive alterations induced in collagen by scurvy and experimental lathyrism, as well as by ageing, are accompanied by significant changes in the amount of hydroxyproline excreted in urine. Although most of body collagen is relatively inert[10], some fractions of collagen are both synthesized and degraded rapidly[8]. While the latter may or may not be identical with the various soluble collagens[11], several observations suggest that the amount of hydroxyproline excreted in urine reflects the amount of body collagen in these metabolically more 'active' forms. Young animals which have more soluble collagen[12] and a more rapid turnover of collagen[10] than adult animals excrete more hydroxyproline. Both the amount of soluble collagen[13] and the synthesis of collagen are decreased in scurvy[14], and the scorbutic guinea pigs excreted less hydroxyproline (Table 1). Lathyrogenic agents increase the amount of soluble collagen[15], and the increased hydroxyproline excretion in the β-aminopropionitrile-treated rats probably indicates an increased amount of metabolically active collagen in lathyrism. It is of interest that experimental lathyrism resembles Marfan's syndrome, and that some patients with Marfan's syndrome excrete increased amounts of hydroxyproline[2]. Measurements of urinary hydroxyproline may be a useful index of collagen metabolism in a number of other experimental and clinical conditions.

PHYSIOLOGY

Analogues of Glutamic and γ-Amino-*n*-butyric acids having Potent Actions on Mammalian Neurones

NUMEROUS investigations have shown that certain amino-acids, including several which are present in the mammalian central nervous system, strongly influence the behaviour of neurones when applied extracellularly[1-4]. These amino-acids fall into two groups; neutral amino-acids related to γ-amino-*n*-butyric acid (GABA), which depress the activity of neurones, and acidic amino-acids related to glutamic acid, which excite neurones[3]. An analysis of the effects of these substances on mammalian spinal neurones indicates that whereas the mechanism of action of GABA differs from that of mammalian inhibitory transmitters[5], the action of L-glutamic acid has certain features in common with that of excitatory transmitter substances[3,6]. Recently, several substances were found to have a much greater potency than GABA and glutamic acid as depressants and excitants respectively of neurones within the isolated and sagitally hemisected spinal cord of the toad[7]. In particular, *N*-methylaspartic acid and homocysteic acid were found to be potent excitants, and 3-amino-1-propanesulphonic acid was a powerful depressant. The potencies of these and related amino-acids on mammalian spinal and cortical neurones have now been determined.

Two methods were used. In the experiments on spinal cord, the amino-acids were passed electrophoretically from solutions of appropriate *p*H into the immediate extracellular environment of interneurones located in the lumbar segments of cats anæsthetized with pentobarbital sodium[3]. Multibarrel electrodes were used so that a comparison could be made between the actions of different substances. In these experiments excitation was measured by the frequency of spike discharge evoked by a particular amino-acid and depression by the degree to which synaptically evoked spikes and negative field potentials were reduced in number and magnitude respectively[3]. Relative potencies were assessed on the basis of the electrophoretic currents required to produce a given degree of excitation or depression. The acidic amino-acids were readily passed as anions from electrode solutions adjusted to *p*H 8 with sodium hydroxide. All these compounds were in a similar ionic state at this *p*H and the concentrations of the substances obtained in the extracellular fluid can be assumed to be directly proportional to the electrophoretic currents used[8]. The relative potencies are given in Table 1, *A*.

Difficulty was experienced in passing the neutral amino-acids as anions, presumably because of electro-osmotic influences tending to pass the substances in the opposite direction when the electrodes contain solutions of high *p*H (ref. 3). These amino-acids were therefore passed as cations from solutions made to *p*H 2·8 with hydrochloric acid. Under these conditions less of the sulphonic than of the carboxylic amino-acids are in the cationic form, and the extracellular concentrations attained by the former, using a particular electrophoretic current, were probably considerably lower than those of the carboxylic acids. It is therefore probable that the true potencies of 3-amino-1-propanesulphonic acid and of taurine, relative to GABA and β-alanine, exceed the figures given in Table 1, *C*.

Table 1. RELATIVE POTENCIES OF AMINO-ACIDS

Excitants	*A*	*B*	Depressants	*C*	*D*
L-Aspartic acid	3	$> 10^{-2}$ *M*	β-Alanine	3	$7 \cdot 5 \times 10^{-3}$ *M*
D-Aspartic acid	2	$> 10^{-2}$ *M*	Taurine	2–3	$7 \cdot 5 \times 10^{-3}$ *M*
L-Glutamic acid	3	$> 10^{-2}$ *M*			
			γ-Amino-*n*-butyric acid	3	$2 \cdot 5 \times 10^{-3}$ *M*
D-Glutamic acid	2	$> 10^{-2}$ *M*			
			3-Amino-1-propane-sulphonic acid	6–15	2×10^{-5} *M*
N-Methyl-L-aspartic acid	2	$7 \cdot 5 \times 10^{-3}$ *M*			
N-Methyl-D-aspartic acid	20–30	$7 \cdot 5 \times 10^{-5}$ *M*			
L-Cysteic acid	3	$> 10^{-2}$ *M*			
D-Cysteic acid	1–3	$> 10^{-2}$ *M*			
L-Homocysteic acid	4–5	not tested			
D-Homocysteic acid	9–18	$2 \cdot 5 \times 10^{-4}$ *M*			
DL-Homocysteic acid	6	5×10^{-4} *M*			

Columns *A* and *C*, approximate relative potencies based on the responses of spinal interneurones to electrophoretically applied amino-acids. Column *B*, minimum concentrations of the amino-acids in Ringer solution required to produce spreading depression within exposed parietal cortex; topical application. Column *D*, minimum concentrations of the amino-acids in Ringer solution required to abolish negative phases of positive–negative potential evoked in parietal cortex by transcallosal stimulation; topical application.

In the cortical experiments, the amino-acids were applied as serially diluted solutions in buffered mammalian Ringer solution (*p*H 7·0–7·2) to the exposed parietal cortex of cats anæsthetized with pentobarbital sodium, and electrical records were obtained from the same cortical surface. The equivalent concentrations of depressants listed in Table 1, *D* are the average of those which just abolished the negative phase of the positive–negative potential sequence evoked by transcallosal stimulation[9]. The equivalent concentrations of excitants (Table 1, *B*) are the average lowest concentrations which produced spreading depression within two minutes of application, this phenomenon being indicated by the abolition of transcallosally evoked responses and the recording of a surface negative potential of 6–12 mV.[2,10]. A pore type of electrode permitted the recording of cortical potentials while the solutions were being applied[10].

Although many factors may limit the quantitative reliability of each of these methods, there is nevertheless a clear qualitative correlation between the two sets of results. It is apparent that 3-amino-1-propanesulphonic acid is considerably stronger than GABA, β-alanine or taurine, which were previously considered to be among the most potent of the amino-acids having depressant actions on mammalian spinal neurones[3]. 3-Amino-1-propanesulphonic acid bears the same structural relationship to homocysteic acid as GABA bears to glutamic acid, and the strong excitatory action of homocysteic acid was therefore to be expected[3]. The D-form of this compound is stronger than the L-form. A similar, though very much larger, difference is evident between the two enantiomers of *N*-methylaspartic acid, the D-isomer in this case being the most potent amino-acid excitant yet tested. The potency of *N*-methyl-D-aspartic acid is more remarkable when it is considered that alkylation of members of both the excitant and depressant series of amino-acids has usually led to lower activity[3,7]. The significance of these results in relation to the general mechanism of amino-acid excitation and depression, including the possible participation of membrane phospholipids in such processes, will be discussed elsewhere.

Inhibition by Potassium of the Mechanical Responses of Frog Muscles at Low Temperature

Csapo and Wilkie[1] reported a curious effect of temperature on the twitch tension in the frog's sartorius muscles, as influenced by the action of 24 m*M* potassium chloride. The onset of the fall of tension development and the depolarization were delayed by lowering the temperature from 23° to 2° C., corresponding to a Q_{10} of 1·2–1·3. On the other hand, the rate of recovery, when normal Ringer solution was replaced, was very much reduced at lower temperature. However, if the recovering muscle were suddenly warmed again, the twitch tension recovered immediately. Grieve[2] has shown that, when recovery was delayed, it was due to delayed re-polarization. If chloride were replaced by the impermeant methyl sulphate, then there was no delay in re-polarization that could not be accounted for by diffusion in the interspaces.

I have studied the inhibition by potassium of isotonic twitching and contractions provoked in the sartorius and rectus muscles. The methods have been described[3]. The muscle was placed into a double-wall muscle chamber, cooled in its outer compartment by a fluid at −2° C.; the solution inside the chamber decreased in temperature from 20° to 0° C. within 2 min.

Both the sartorius and the rectus muscle were unable to give twitch or phasic contracture-like responses comparable in height to the control muscles, after application of potassium chloride or potassium sulphate lasting 1 min. or more, unless the time of recovery was 5–10 min. After 40 sec. of recovery, only 23 per cent of the control height of the contractions was obtained in the sartorius, when 115 m*M* potassium chloride or 95 m*M* potassium sulphate were applied, 4 per cent of the twitch response when 20 m*M* potassium chloride was applied and 15 per cent of the rectus first phase response[3] when 6–10 m*M* potassium chloride was applied. After the same solutions were allowed to act for the same intervals at low temperature, and the subsequent time of recovery of 40 sec. occurred at room temperature, the corresponding responses were several times larger, the percentage values being 63, 69 and 70. Responses of the same magnitude as the percentages mentioned were obtained if the action of potassium chloride or potassium sulphate at the lower temperature was prolonged in the sartorius about three times (contractures) and in the rectus for more than five times (Fig. 1).

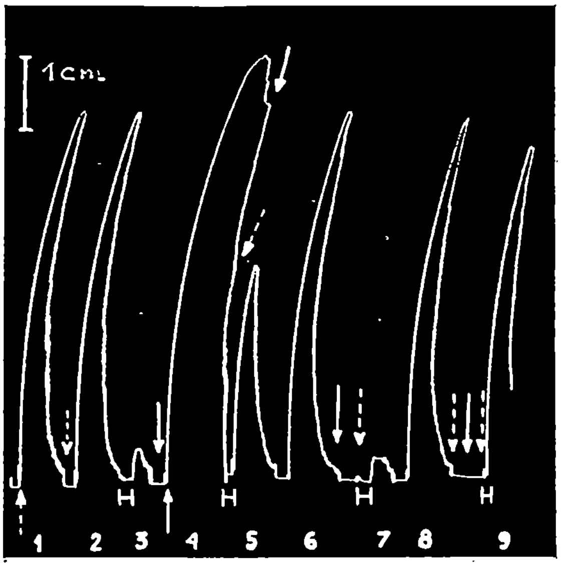

Fig. 1. Frog's rectus. Phasic response to 10 m*M* potassium chloride; 0·5 m*M* calcium in Ringer solution. Arrows upward, application of potassium; arrows downward, washing; full arrows, cold solutions (0° C.); interrupted arrows, solutions at room temperature (20–23° C.). *H*, Short interval (40 sec.); 1, 2, 3, control reactions; 4, 5, reaction at low temperature and, a short time after it, at room temperature; 6, after a reaction at room temperature, washing (15 min.) at low temperature, 40 sec. before 7, at room temperature; 8, after the reaction, first a 10-min. wash at room temperature, then at low temperature, 40 sec. before 9, again at room temperature

Low temperature, if applied a few seconds after the exposure to potassium had been terminated, prolonged the inhibition by potassium: no significant recovery could be obtained at 0° C. for 20 min. of washing. The same results were obtained with potassium chloride as well as with potassium sulphate. No rapid recovery within 40 sec. of warm washing, after prolonged washing in a cold Ringer solution, was observed.

The inhibiting action of potassium on mechanical responses at low temperature in the present experiments seems to follow a course which is slowed down relatively more than that of the decrease in twitch tension. The absence of a rapid recovery during the short period, after warming up, and the lack of differences in the rate of recovery after application of potassium chloride and potassium sulphate, prove that the two processes may indeed be different.

In a further group of experiments the response of the sartorius muscle to potassium was examined, after prolonged washing (20 min.) in a cold calcium-free solution. The effect was the same as that at room temperature, that is, the contraction was inhibited[4]. If the muscle were washed first in a calcium-free Ringer solution at room temperature, then cooled and washed in a cool, Ringer solution containing calcium, it regained the ability to respond to potassium by a contraction.

Fatigue in a Fluid-filled Pulsating Elastic Tube

Experiments with the 'oscillator' described by me[1] have shown that fatigue affects the elastic tube, after it has been pulsating for several hours.

Aneurysmal-like bulges may occur. Alternatively, a small hole forms at the end close to the rigid outlet tube, presumably due to cavitation occurring in contact with the wall. Fluid may escape from this hole, or air be sucked in, at each pulse.

A remarkable effect is obtained by the application of cedar wood oil. Within a few minutes, the distal segment of the elastic tube, when so treated, becomes permanently stretched into a sigmoid shape and develops periodic constrictions and dilatations, affecting the system of short wave-length, that is in the range 1–2 cm.

These figures resemble the shapes of arteries in atherosclerosis.

PHARMACOLOGY

Alleged Anticomplementary Effect of Aspirin

Van Oss *et al.*[1] recently reported that aspirin at concentrations of $2 \cdot 2 \times 10^{-3}$ *M* (40 mgm./100 ml.) inhibited the lysis of red cells in a simple complement-hæmolysis reaction, but that sodium salicylate was inactive. This was interesting in view of the therapeutic action of aspirin against diseases such as the rheumatic disorders which are thought to involve immunological phenomena[2]. Two other related compounds, salicylaldoxime and salicylaldehyde, were earlier reported[3] to inhibit red cell lysis in a similar reaction. I therefore investigated the complement-hæmolysis technique since it might usefully predict anti-rheumatic activity in other salicylate derivatives.

Sheep erythrocytes (*E*), anti-sheep erythrocyte serum prepared in the rabbit (*A*) and complement (*C′*) were standard serological reagents obtained from the Commonwealth Serum Laboratories, Melbourne. Complement was received as ampoules of freeze-dried guinea pig serum which was reconstituted with distilled water and stored at 4° C. It gave results identical with fresh guinea pig serum prepared in these laboratories. Barbital buffer, *p*H 7·4 and containing added Mg^{++} and Ca^{++}, was prepared according to Mayer *et al.*[4] and diluted 1 in 5 with distilled water on the day of use. All reagents were diluted in barbital buffer. When 0·1 ml. of a 2 per cent suspension of washed erythrocytes was sensitized with 0·1 ml. of antiserum 1/1,000, the addition of 0·5 ml. of guinea pig serum 1/200 caused complete hæmolysis of the erythrocytes within 30 min. at 37° C. The effect of added substances on the progress of the *C′* hæmolysis was determined by placing 0·25 ml. of guinea pig serum 1/100 into hæmolysis tubes and adding 0·25 ml. of a solution of the compound in barbital buffer. The latter solution was replaced by buffer alone in control tubes. The diluted antiserum and red blood cells were then added and the tubes incubated at 37° C. for 30 min. The *p*H of the solutions prior to incubation was determined with a glass electrode in duplicate tubes, which were prepared for each concentration of the compound under test.

The substances I have investigated and the concentrations that caused an approximate 50 per cent inhibition of hæmolysis in our procedure are shown in Table 1. All the acids decreased the *p*H of the final mixture proportional to their concentration, and the *p*H range at the concentrations where hæmolysis was inhibited are shown in column 2. Where applicable I have included the inhibitory concentrations reported by other workers for comparison.

Table 1. SUBSTANCES WHICH INHIBITED COMPLEMENT-HÆMOLYSIS AND THEIR EFFECT ON THE *p*H OF THE REACTION MIXTURE

Compound	Concentrations (molar) giving 50 per cent inhibition of hæmolysis in 30 min.	*p*H ranges of the reaction mixtures at the inhibitory concentrations	Concentrations (molar) elsewhere reported to inhibit complement-hæmolysis	Ref. No.
Aspirin	$2\text{–}3 \times 10^{-3}$	5·8–6·4	$2 \cdot 2 \times 10^{-3}$	1
Salicylic acid	$2\text{–}3 \times 10^{-3}$	5·8–6·4	10 per cent inhibition $3 \cdot 3 \times 10^{-3}$	
Sodium salicylate	No inhibition	7·4	No inhibition	1
Fumaric acid	$2\text{–}3 \times 10^{-3}$	5·8–6·2	—	—
Hydrochloric acid	$2\text{–}3 \times 10^{-3}$	5·8–6·4	—	—
Salicylaldoxime	8×10^{-4}	7·5	5×10^{-4}	3
Salicylaldehyde	$8 \times 10^{-4}\text{–}10^{-3}$	7·3	$2 \cdot 5 \times 10^{-4}$	3

Several important points emerge from Table 1. The capacity of the diluted Mayer solution was clearly inadequate to buffer the effects of the acidic compounds on the *p*H of the hæmolytic reaction. Furthermore, it seemed strange that while salicylic acid inhibited hæmolysis, sodium salicylate at similar concentration was inactive—yet at *p*H values above 5, both compounds would be in solution in identical form as salicylate ions. Finally all the acids tested inhibited my hæmolytic reaction at approximately the same molar concentration ($2\text{–}3 \times 10^{-3}$), hydrochloric acid being just as effective as the organic acids. At this concentration they reduced the *p*H of the reaction from 7·4 to about 6. It appeared likely therefore that inhibition of hæmolysis was due in some manner to the *p*H shift rather than a specific anticomplementary action. This explanation was further justified when the above experiments were repeated using undiluted Mayer buffer, the tonicity of which was adjusted by omitting some of the sodium chloride. Under these conditions hæmolysis was complete within 30 min. in the absence of a test compound and was inhibited by salicylaldehyde and salicylaldoxime at the same concentrations as in the dilute buffer. However, none of the other substances in Table 1 lowered the *p*H of the final mixture below 7·0 or caused any inhibition of complement-induced hæmolysis at concentrations below 5×10^{-3} *M*. Subsequent investigation with buffers of even greater capacity for hydrogen ions failed to show an anti-complementary effect of the acids in the absence of *p*H shifts at concentrations up to 10^{-2} *M*.

In conclusion, my results suggest that aspirin has no real effect *per se* on complement-induced hæmolysis of red blood cells. Since it is a weak acid, it may, if it is insufficiently buffered, lower the *p*H of a complement-hæmolysis reaction to the point where there is an unspecific inhibition of hæmolysis. The ability to do this is probably common to all acids.

It is of some interest that the anticomplementary effect of aspirin has been reported to occur also *in vivo*[1]. However, since no details were given, no comment is possible.

HISTOLOGY

Neurosecretion and Granules in Neurones of the Brain of the Leech

EXAMINATION of established neurosecretory structures with the electron microscope reveals characteristic cytoplasmic structures: the elementary neurosecretory granules. These granules are usually electron-dense and range in diameter from about 1000 Å. to about 3000 Å. Mean granule diameters differ from cell to cell in the same and in different species; but the fully formed granules are of relatively constant size for each cell type.

The elementary neurosecretory granule has been found in a variety of neurohæmal organs in representatives of many animal groups: the pars nervosa of vertebrates (mammal[1], bird[2], reptile[3], amphibian[4], and teleost[5]), the corpus cardiacum of insects[6], the sinus gland[7] and the post-commissural organ[8] of crustaceans. More recently, similar granules have been observed in the perikarya of neurosecretory cells of the caudal neurosecretory system of teleosts[9], of the preoptic nucleus of teleosts and amphibians[10,11], of the pars intercerebralis of insects[11,12], and of the brain of annelids[11,13]. The ubiquity of these elementary granules in neurosecretory systems has led to the conclusion that their presence may be virtually diagnostic of neurosecretion at the ultra-structural level.

Examination of the brain of the leech, *Theromyzon rude*, with the electron microscope reveals that every neurone contains at least some granules in the size range of elementary neurosecretory granules. (Electron microscope observations were made of the supra-œsophageal ganglion of *Theromyzon rude* fixed in Palade fixative with sucrose, embedded in methacrylate, sectioned on a Porter-Blum microtome, and observed with an R.C.A. *EMU*-3 electron microscope.) However, with the light microscope three principal types of neurones can be distinguished[14]. Two of these cell types contain cytoplasmic inclusions suggestive of intense glandular activity; cells of the third type, comprising the vast majority (95 per cent) of the neurones of the brain, show signs of minimum glandular activity only. Axons from the secretory-appearing cells pass into the dorsal commissure and appear to terminate in a neurohæmal area at its posterior surface. With the electron microscope at least some of the glandular-appearing neurones contain enormous numbers of elementary neurosecretory granules, both in the cell body and in the axon (Fig. 1). In the presumed neurohæmal area, the elementary neurosecretory granules become

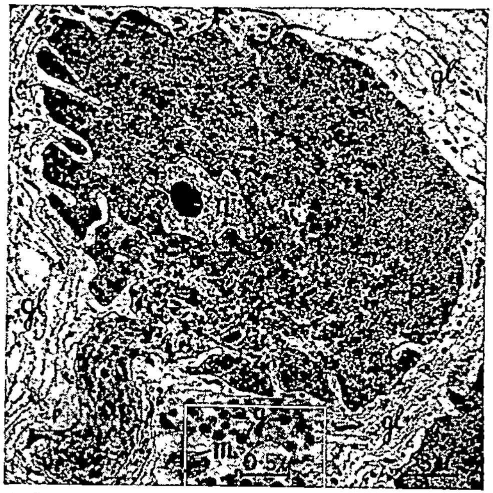

Fig. 1. Section through a neurone from the leech brain. Numerous dark neurosecretory granules are present in the cytoplasm and axone. *n*, Nucleus with a nucleolus; *a*, axon; *gl*, glia cell cytoplasm; *p*, polystyrene particle (2640 Å.). Insert. Portion of cytoplasm from a similar type of cell. *g*, Neurosecretory granules; *m*, mitochondrion

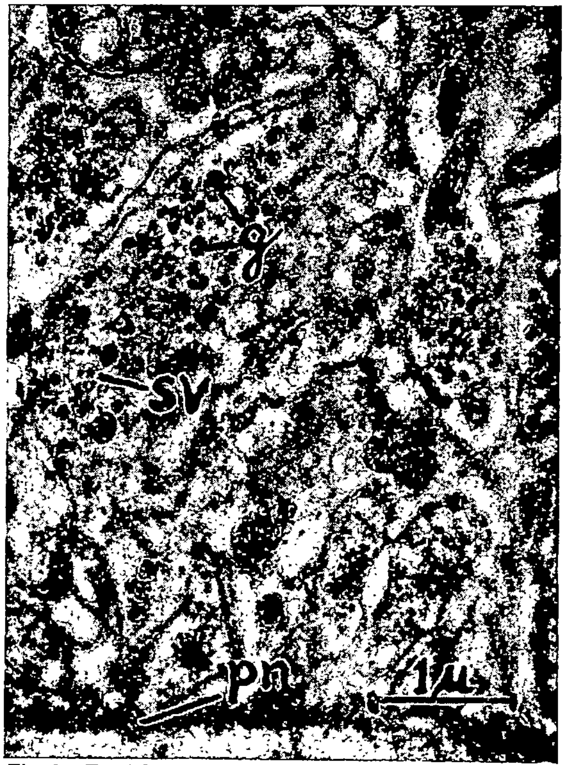

Fig. 2. Frontal section of the posterior portion of the dorsal commissure. Shown are axon endings of presumed neurohæmal structure. *g*, Neurosecretory granules; *sv*, synaptic vesicles; *pn*, perineurium

intermixed in the axones with small vesicles morphologically equivalent to synaptic vesicles (Fig. 2). Such vesicles have been reported in other neurohæmal structures[1,2,4].

On the basis of ultrastructural cytological criteria, including the consistent association of elementary granules with Golgi membranes[11], all neurones in the brain of the leech would have to be defined as neurosecretory. Since the majority of neurones in the brain must be involved in 'ordinary' nervous activities, one is hesitant to ascribe neurosecretory activity to all of them. It is possible that some of the types of granules in the leech neurones may be associated with neurotransmitter function. The usual synaptic vesicle is small (< 500 Å.)[15] and relatively electron-lucent. However, our knowledge of the range of size and appearance of presumed neurotransmitter granules is limited, particularly with respect to non-cholinergic neurones. Conceivably many of the larger, more electron-dense granules seen in leech neurones could be synaptic granules of a type associated with non-cholinergic neurohumours. Only those granule-bearing cells terminating in the neurohæmal area would be considered as properly neurosecretory.

The advice and critical reading of this communication by Prof. Howard A. Bern are gratefully acknowledged. The work was aided by grant *G*-8805 from the National Science Foundation.

PATHOLOGY

Stimulation by Heparin of Parenchymal Liver Cell Proliferation in Normal Adult Rats

IT has been reported[1] that serum from hepatectomized rats when injected into normal rats will stimulate mitosis in the livers of the recipients. This finding could not, however, be confirmed by other workers[2]. In work reported earlier[3], we found that plasma from hepatectomized rats, which was collected using heparin to prevent clotting, stimulated both mitosis and deoxyribonucleic acid (DNA) synthesis in rat liver parenchymal cells, when injected into normal rats. On the other hand, serum or citrated plasma from hepatectomized rats had no apparent stimulating effect. For this reason, the effect of heparin itself on the proliferation of normal rat liver was examined.

Groups of five male Holtzman rats, 250–280 gm. body-weight, were used in each experiment. In a typical experiment, 100 units of heparin in 3 ml. of physiological saline or saline alone was injected intraperitoneally. If mitotic activity in the liver was to be examined, the animals were killed 24 hr. after the sample injection. Paraffin sections were cut at 6μ and stained with Harris's hæmatoxylin. Mitotic activity in parenchymal liver cells was expressed as mitotic figures in 50 high-power fields (× 400).

The effect of heparin on DNA synthesis in the liver was determined by intraperitoneal injection of orotic acid-6-^{14}C (2·5 μc./rat) 7 hr. after sample injection. The animals were killed 17 hr. later and DNA isolated essentially by the method of Hecht and Potter[4]. Isotope measurements were made using a Nuclear Chicago *D*47 gas-flow counter equipped with a 'Micromil' window. Specific activity is expressed as counts/min. per mgm. DNA.

Table 1. EFFECT OF HEPARIN AND OTHER SULPHATED POLYMERS ON DNA SYNTHESIS AND MITOTIC ACTIVITY IN NORMAL ADULT RAT LIVER

Sample injected	Mean mitotic index		Mean specific activity (c.p.m./mgm. DNA)		
	Exp. I	Exp. II	Exp. III	Exp. IV	Exp. V
Saline control	6 (1–11)[*]	6 (1–11)	15 (8–20)	18 (10–23)	9 (4–16)
Heparin (100 units)	62 (26–113)	74 (27–113)	68 (27–113)	92 (45–162)	64 (30–136)
Heparitin sulphate	—	—	—	—	115 (30–208)
Chondroitin sulphate *B*	—	—	—	—	34 (16–60)
Chondroitin sulphate *A*	—	—	—	—	19 (12–26)
Chitin sulphate	—	—	—	—	15 (9–22)
Polystyrene sulphonate	—	—	—	—	5 (4–7)

[*] Range in parentheses.

The results obtained from representative experiments using heparin are shown in Table 1. It is apparent that intraperitoneal injection of heparin resulted in marked stimulation of mitotic activity in normal rat liver parenchymal cells. The increase in mitotic activity is accompanied by increased incorporation of the radioactive precursor into DNA. Microscopic examination showed no apparent alteration in liver structure under these conditions.

To determine whether the response of the liver was specific for heparin, a number of natural and synthetic sulphated polymers were also examined for their ability to stimulate DNA synthesis in the liver (Table 1). One mgm. of each polymer in physiological saline was administered under the same conditions described here. Heparitin sulphate, which differs in structure from heparin only slightly[5], having some of the *N*-sulphate groups replaced by *N*-acetyl, stimulated liver DNA synthesis to the same extent as heparin. The higher value of the single experiment cited is not significant. Chondroitin sulphate *B* (β-heparin) also had some activity in this system, whereas, chondroitin sulphate *A*, chitin sulphate and polystyrene sulphonate had little or no stimulating effect. There was no change in this pattern on increasing the dose to the 5-mgm. level. The ability of the various polyanions to stimulate liver DNA synthesis appears to parallel the anti-coagulant and lipæmia-clearing activity of these substances.

The marked stimulation of liver-cell proliferation by heparin at doses above 20 units/rat suggests that

EXPERIMENTAL NUCLEAR CHEMISTRY

by G. R. Choppin

Teaches the techniques and necessary basic theory for utilization of radioisotopes in scientific research and experimentation. Employs numerous experiments and techniques, using AEC license-free quantities of radioisotopes. Includes treatment of latest counting equipment, with particular reference to the simple Geiger counter for experimental use. Appendices concern isotope procurement and regulations, equipment and availability. 63/-

GAMES OF STRATEGY: Theory and Applications

by Melvin Dresher

Explores an elementary, mathematical treatment of the relatively new branch of mathematics, the theory of games of strategy. Relates rigorous theories of rational behaviour and planning within competitive environments. Problems and worked-out solutions serve to present complete theories and significant results. 42/-

SOVIET POWER: Energy resources, Production and Potentials

by J. A. Hodgkins

Surveys geographically energy resources and solid fuel reserves, their production and potentials in the Soviet Union today. Indicates the U.S.S.R.'s technical and industrial capacity with stress upon the extensive development of power bases and energy resources. Traces Soviet growth in coal, oil, natural gases and total energy potential in relationship to expanded economic programmes. 25/-

Use of Desertomycin Medium in Routine Selective Isolation of Fungi Pathogenic to Man

THE isolation of pathogenic fungi producing superficial or systemic diseases in man from clinical materials is made difficult by different contaminating bacteria and saprophytic fungi overgrowing the culture medium and suppressing or inhibiting the growth of pathogenic fungi. In order to obtain pathogenic fungi in a pure culture, attempts were made to mix various substances in the medium in such a way that they would be liable to prevent the growth of contaminants. After a great deal of effort, the most satisfactory result was obtained by cultivation media containing actidione. Actidione (cycloheximide)[2] was the only antifungal antibiotic which, though exerting no antibacterial effect, inhibits the growth of most saprophytic fungi, yet does not inhibit the development of fungi pathogenic to man. For this very reason, it can be used with penicillin and streptomycin[2,3] or chloramphenicol[4] for the preparation of selective culture media.

The antibiotic isolated from *Streptomyces* and a completely new type called desertomycin, which is produced by us in a crystalline form, reveals a selective anti-fungal effect similar to actidione. Previously we reported on its anti-bacterial and cytostatic effect *in vitro*[5,6]. Our recent investigations, however, disclosed also its anti-fungal effect *in vitro*. Its anti-fungal effect on saprophytic fungi is much stronger than on fungi pathogenic to man. The anti-fungal concentration inhibitory to various fungi of desertomycin incorporated in Sabouraud–dextrose–agar was as follows: (*A*) *Streptomyces* strains: 1–10 μgm./ml. (*B*) Most of phytopathogenic and saprophytic filamentous fungi: 10–25 μgm./ml. (*C*) Dermatophytes: 50–100 μgm./ml. (*D*) Yeasts and yeast-like fungi (except *C. neoformans*): 250–500 μgm./ml.

By dint of its previously disclosed anti-bacterial property and the selective anti-fungal effect revealed by the findings, desertomycin promised to be a suitable agent for preparing culture media on which fungi pathogenic to man can be cultivated in pure culture.

These investigations were completed with cultivations of clinical materials liable to produce fungal contamination (such as hair, skin-scrapings, nail-clippings, sputum, etc.). The clinical materials were inoculated partly on Sabouraud-agar containing no antibiotics and partly on Sabouraud-agar containing desertomycin of 30 and 50 μgm./ml. The tubes were usually incubated for three weeks at 27° C., and the cultures were read. The results are summarized in Table 1.

Table 1

Total No. of materials	Total No. of isolations	Positive on both agars	Positive on desertomycin agar, negative on Sabouraud-agar
308	77	24	53

77 isolates were obtained from a total of 308 substances. 24 cultures of dermatophytes were obtained on both Sabouraud- and desertomycin-agars. 53 cultures of fungi pathogenic to man were isolated on desertomycin media but not on the corresponding tubes of Sabouraud-agar. These results reveal the superiority of desertomycin-containing medium to Sabouraud-agar as a routine isolation medium for fungi pathogenic to man from clinical materials.

Although desertomycin differs altogether from actidione in its chemical, physical and some biological properties, the two antibiotics closely resemble one another in their selective anti-fungal characteristics. Both can be used for the selective isolation of fungi pathogenic to man. The disadvantage of desertomycin as against actidione is that its quantities inhibitory to the growth of pathogenic and apathogenic fungi do not differ so much. On the other hand, desertomycin possesses several advantageous properties as against actidione, such as (1) stability; resistance to heat; it can be autoclaved with the culture medium without loss of activity; (2) it has also an anti-bacterial effect and so does not require the addition of any anti-bacterial antibiotic; (3) about one-tenth of the concentration is needed to attain the same effect as in actidione; (4) it does not irritate or damage the skin.

As a result of these findings, the culture medium containing desertomycin provides new possibilities for dermato-mycological laboratories. Detailed description of the experiments will be reported elsewhere.

RADIOBIOLOGY

Radiation Sensitivity of *Escherichia coli* to β-Rays in Dry and Wet Condition

THE greater sensitivity of biological material to irradiation in the wet condition is due to the formation of radicals in the water surrounding the vital molecule. However, all the volume is not effective, since these radicals have a definite life-time and can diffuse only to a distance allowed by that time. This diffusion distance has variously been estimated from different types of inactivation studies in the wet and in the dry state of the molecules. Recently, the dependence of this distance on the shape of the molecule has been reported, and it has been shown that as the asymmetry of the target increases, the

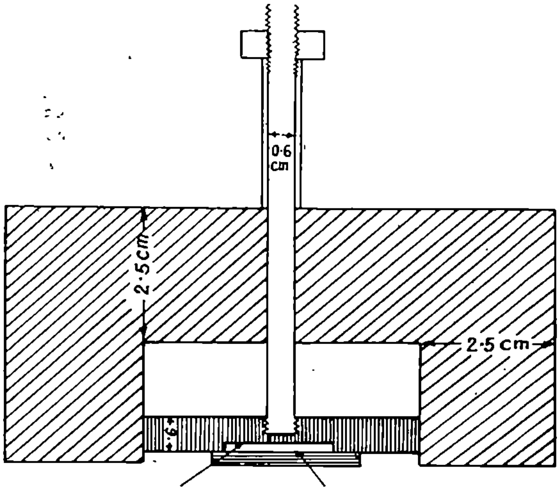

Fig. 1. Arrangement of β-irradiation of *E. coli* from strontium-90 source

diffusion distance decreases[1]. In the present report this idea has been applied to the calculation of diffusion distance for the inhibition of colony-formation by *E. coli* exposed to β-rays from strontium-90.

E. coli was grown in peptone water (peptone 1 per cent, sodium chloride 0·5 per cent in distilled water) for 4 hr. at 37° C. At the end of this period, bacteria were freed from the culture medium by repeated centrifugation and washing with Sørensen's buffer ($M/15$ KH_2PO_4 and $M/15$ Na_2HPO_4 3 : 7 v/v) at *p*H 7·00. This cell suspension, freed from broth medium, was used in different experiments.

The source of β-irradiation (obtained from the Radiochemical Centre, Amersham, England) was a strontium-90 plaque 2 cm. × 2 cm., as shown in Fig. 1. It was kept in a lead-lined 'Plexi-glas' box, the distance between the source and the sample being controlled by an adjustable screw. The total distance between the source and the sample was 2 mm.; the dose at this distance measured with an extrapolation ionization chamber was 2,460 ± 368 rads/min.

For irradiation in the wet condition, glass slides were covered with thin films of gelatin and one drop of mother suspension was taken on the slide. These glass slides containing the bacteria could be placed under the β-source in the specified position shown in Fig. 1, the centre of the drop being accurately in line with the centre of the sources. For irradiation in the dry condition, the gelatin covered glass slides containing bacteria were first dried in a vacuum desiccator for 48 hr. The preliminary tests for desiccation and the conditions of viability of the bacteria after the desiccation process have been described in detail in a previous paper[2].

Slides prepared in exactly identical ways, but not subjected to irradiation, were kept as controls. Agar platings were done by releasing bacteria both from the control and the irradiated slides separately in known quantities of phosphate buffer. Visible colonies were counted after 24 hr. of incubation at 37° C. in order to obtain the viable count in the control and irradiated samples. The ratio N/N_0 could thus be obtained for each dose of radiation, both in the wet and in the dry condition of irradiation.

Fig. 2 shows the results of irradiation of *E. coli* in dry and wet condition, with β-rays from strontium-90. 37 per cent survival doses in dry condition is 20,000 rads and that in the wet condition is 6,000 rads. If the inactivation is due to a single-hit type of process and there are n equally sensitive targets per cell the survival ratio $S = N/N_0$ after dose of D rads is given by:

$$S = \exp - [I \sigma n V] \qquad (1)$$

where $I = 5{\cdot}68 \times 10^{11} \times D$ primary ions per c.c. of unit density material, σ, the density of the material and V, the volume of the target responsible for inactivation. From the relation (1) the target volumes are found to be $6{\cdot}6 \times 10^7$ Å.^{3} and $29{\cdot}3 \times 10^7$ Å.^{3} for dry and wet conditions respectively. The density of the target material in the dry and wet condition has been assumed to be 1·33 and 1·00 respectively. Additional sensitive volume ΔV in the hydrated condition is thus $22{\cdot}7 \times 10^7$ Å.^{3}. For n equally radiation-sensitive targets per cell the additional sensitive volume is given by:

$$\Delta V = nYqv \qquad (2)$$

where Y is the number of radicals formed per primary ionization in water, q the probability of reaction between the radicals and the target and v is the effective volume of water from which the radicals can come and react with the target.

The mechanism of the inhibition of division by radiation is not clear. Very possibly it is a gene-controlled process, so that the action of radiation on any one of the sub-units of DNA molecules located in the chromosomes might be responsible for the inhibition of division[3,4]. A recent estimate of the genetic unit from the transforming principle activity is 20 Å. in diameter and 3400 Å. in length[5], giving a volume $V = 10^6$ Å.^{3}. This leads to a number $n = 60$ from the experimentally observed total volume $nV = 6{\cdot}6 \times 10^7$ Å.^{3}. For the inactivation of DNA, the value of effective radicals formed per primary ionization Yq is 1·5 (refs. 6 and 7).

The volume of available water per target v is obtained from equation (2) as $2{\cdot}5 \times 10^6$ Å.^{3}. Con-

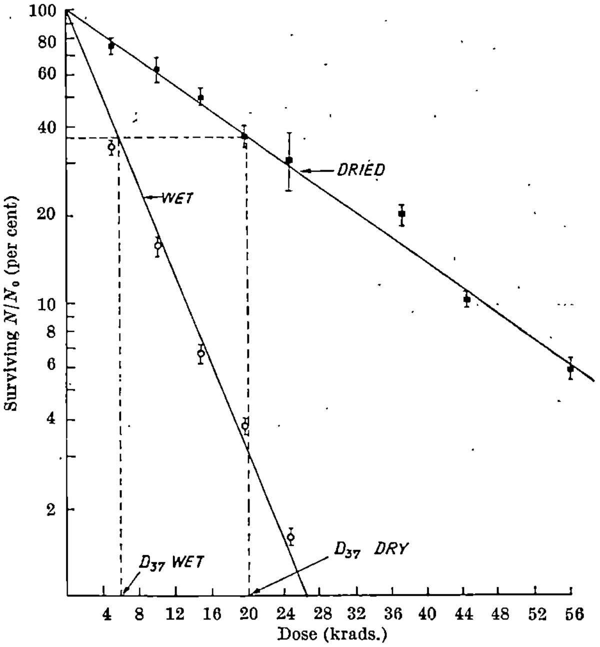

Fig. 2. Dose-survival curves of *E. coli* in dry and wet condition exposed to strontium-90 β-particles

sidering the maximum value of hydration as 40 per cent for protein, the hydration volume per target is $0{\cdot}44 \times 10^{6}$ Å.^{3}. The excess water $2{\cdot}1 \times 10^{6}$ Å.^{3} per target must be outside the target and not inside. Assuming the distribution of this water in a uniform layer around the target, the thickness of water surrounding each of the hydrated targets comes out to be 6·5 Å. So besides the hydrated target the radicals can come only from 2 or 3 molecules thickness of water.

Gross Beta-Activity in the Thames River (Conn.)

Gross β-radioactivity has been determined in a number of marine organisms in the Thames River, Connecticut, United States. Collection areas were selected on the basis of established beds. Samples have been obtained and assayed every two weeks since April 1960. Organisms were returned to the Laboratory immediately after collection, washed free from surface contamination, weighed wet, dried under infra-red and ashed. Aliquots of the ash were prepared for radioassay and counted in an automatic β-counting system.

Radioassays were conducted on the following organisms: *Crassostrea virginica* (oyster), *Mercenaria mercenaria* (clam), *Mytilus edulus* (mussel), *Modiolus demissus* (mussel), *Laminaria agardhii*, *Fucus vesiculosus*. *Ulva lactuca* and *Chondrus crispus* (algæ). The β-activities obtained from these organisms exhibited seasonal variations, with *Laminaria* showing highest values and the oyster the lowest values.

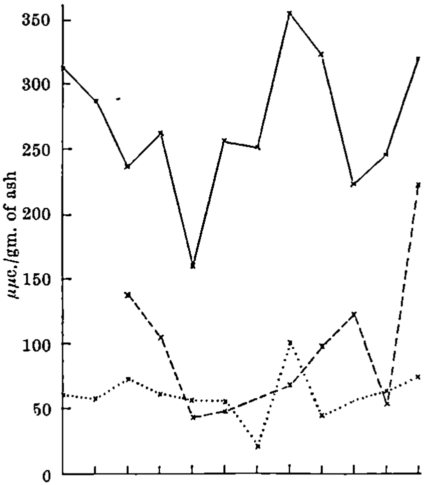

Fig. 1. Radioactivity in organisms obtained from the Thames River (Connecticut). —, *Laminaria agardhii*; · · ·, *Crassostrea virginica*; – –, *Mercenaria mercenaria*

Average monthly radioactive values for three of the above organisms are recorded in Fig. 1. Locations from which these organisms were obtained are: *Laminaria* from a point north of the Electric Boat Co., *Mercenaria* from a bed opposite the United States submarine base and *Crassostrea* from a bed north of the submarine base.

Maximum levels of radioactivity occurred in January 1961, in *Laminaria* with a total of 356 μμc./gm. of ash. Minimum values recorded during the year were in oysters in December 1960, with 23 μμc./gm of ash.

On the basis of analyses for total potassium in these organisms and calculations as to the amount of radioactivity contributed by natural potassium-40 it can be determined that most of the β-activity observed is due to potassium-40. It can be concluded, therefore, that the quantity of radioactivity present in marine organisms studied is extremely small, and does not represent a health hazard.

BIOLOGY

Biological Incorporation of Implant Material in the Rat

When plastic material is used as a biological implant, to improve contour or function, one of four things commonly occurs: it may cause an acute inflammatory episode and be rejected; rejection may be delayed for several months or years; it may be removed piecemeal by the body's own phagocytes; it may become encysted by fibrous tissue and remain *in situ*. In the last situation the implant has become virtually extracorporeal.

During a recent investigation of various plastic materials in rats, a completely new biological reaction, that of incorporation, was noted. The method of investigation was as follows: through a midline incision the abdomen was opened and a square 2 × 2 cm. of peritoneum and muscle was excised from the lateral abdominal wall. The defect created was covered by the material under test and sutured in place. The abdomen was then closed (Fig. 1). Naked-eye and microscopic examination of the implants were made at various times up to three months later.

In six animals a sheet of polytetrafluoroethylene, 0·3 mm. thick, was used. This material appeared to cause very little tissue reaction, and in four rats it became completely encapsulated by fibrous tissue. But in two animals normal peritoneum grew over the material. The histological picture in these two rats was quite unique; the polytetrafluoroethylene sheet had become incorporated within the tissues, with no abnormal cellular reaction. In Fig. 2, normal endothelial cells of peritoneum (*A*) are seen covering the polytetrafluoroethylene (*B*), which is permeated by normal-looking blood vessels and occasional tissue cells. The fibrous nature of polytetrafluoroethylene is evident and on superficial examination gives the appearance of collagen fibres. Deep to the implant is the normal muscle (*C*) of the abdominal wall: at this site there is no fibrous capsule nor cellular reaction to the plastic material. Examination under higher magnification (Fig. 3) confirmed the normal appearance of the blood vessels and cells within the polytetrafluoroethylene, suggesting that this was in fact a 'living implant'.

Measurements made from the histological sections indicated that the polytetrafluoroethylene sheet had increased in thickness by 30 per cent, and moreover it is stained faintly by basophilic dyes whereas before implantation it was not possible to stain this material with any of the routine histology stains. A piece of the original polytetrafluoroethylene sheet was subjected to analysis by Mr. G. W. Bowley, of Imperial Chemical Industries, Ltd., and found to be of good quality made from granular polymer, and there was no change in thickness on heating to relieve internal stresses. One is therefore driven to the conclusion that living matter is able to invade the discontinuous structure of a polytetrafluoroethylene moulding and, in so doing, open up this structure to make it readily porous to water. The effects observed in the biological alteration of the implant are thus due to physical and not chemical causes. Polytetrafluoroethylene, unlike other thermoplastics, does not have any melt state and has to be processed by methods similar to those used in powder metallurgy. Polytetrafluoroethylene fabrications are thus prone to void inclusions. No explanation, however, can be offered for the elongation of the polymer granules into fibres although elongation of particles does occur when the polymer in the dispersion form is processed into tape by extrusion and calendering: but the sheets of polytetrafluoroethylene used as implants has not been processed in this way.

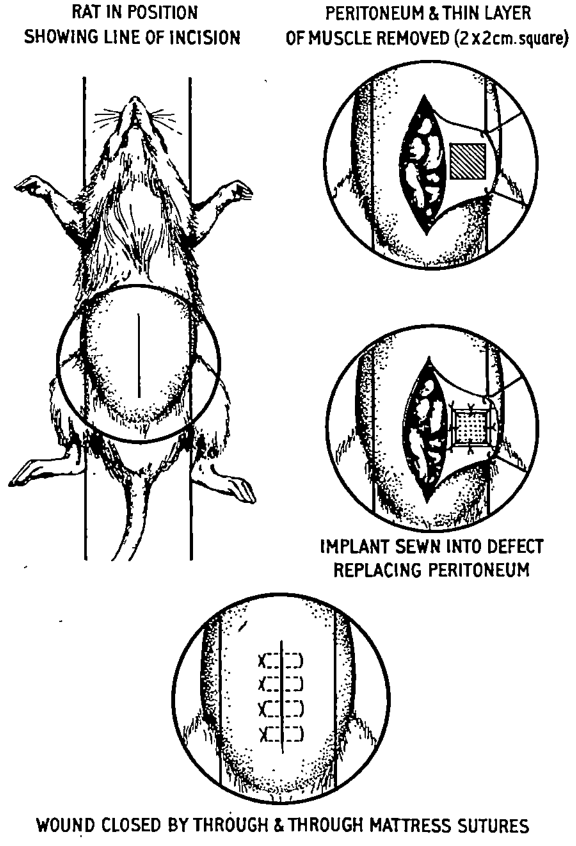

Fig. 1. Diagram of implant techniques

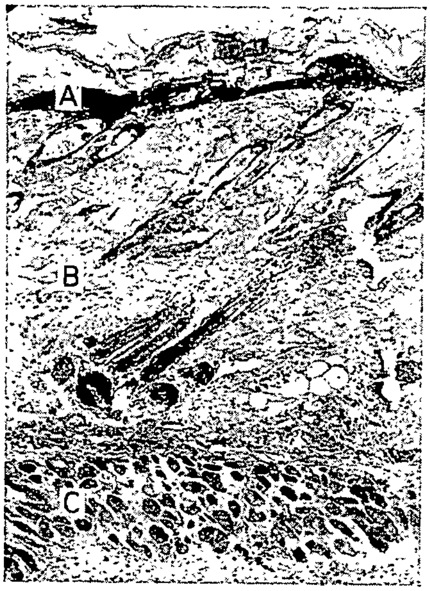

Fig. 2

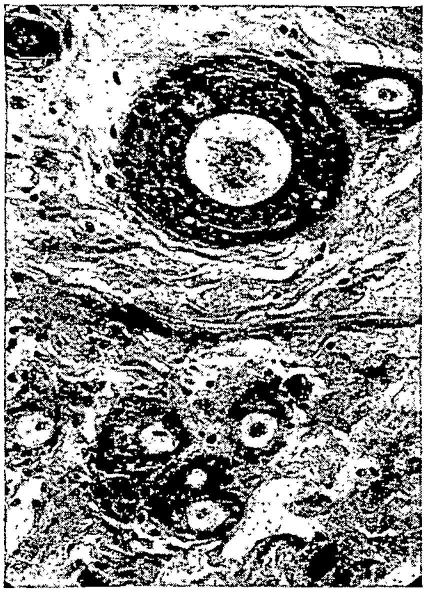

Fig. 3

These findings open up new possibilities for implant surgery.

Rapid Development of Hypomagnesæmia in Lactating Cows given Artificial Rations Low in Magnesium

THE most characteristic biochemical change associated with the disorder of cattle known variously as grass staggers, lactation or nutrition tetany and Hereford disease is a fall in the blood-serum magnesium concentration from a normal value within the range 2·0–3·5 mgm./100 ml. to one of 0·7 mgm. or less. The disorder has its highest incidence in milking cows in spring, shortly after a change from winter rations to the grazing of pasture, and under such conditions frequently the fall in serum magnesium concentration is rapid; in extreme cases serum magnesium values of less than 0·7 mgm./100 ml. are observed within two days of the change of diet.

We[1,2] have previously demonstrated with milking cows that a change from winter rations to grazing is commonly associated with a decrease in the net uptake of magnesium from the gut (magnesium in the feed less the magnesium excreted in the fæces), due to a reduction in the dietary intake of magnesium and, to a lesser extent, to a decrease in its availability to the animal: hypomagnesæmia occurs in animals in which the net uptake of magnesium from the gut is reduced to such an extent that it fails to meet the magnesium requirements of the animal for milk secretion, body retention and fœtal growth, and in which, as a consequence, there is a drain on the small amount (2–3 gm.) of freely available magnesium in the blood serum and other extra-cellular fluids. The rapidity of development of hypomagnesæmia implies that the milking cow, during periods of acute magnesium deficiency, has little ability to mobilize any of the considerable amounts (100–200 gm.) of magnesium present in her soft tissues and bones.

Following the early investigations of Blaxter *et al.*[3], I have made a number of attempts to develop for milking cows artificial diets low in magnesium with the object of determining the effect of a rapid reduction in dietary magnesium on serum magnesium concentration, and of ascertaining the minimum amount of dietary magnesium, in a suitable form, on which an animal can maintain normal serum magnesium concentrations. In such work, two main problems have to be overcome: the technical difficulties of preparing the necessarily large quantities of foodstuffs sufficiently low in magnesium, and the need to ensure that such foodstuffs are acceptable to the milking cow and do not lead to digestive disturbances and subsequent loss of appetite and milk yield. It seemed preferable in the first instance, therefore, to develop rations based largely on feeding-stuffs in common use, but early experiments showed that the inclusion of large amounts of processed feeds low in magnesium, such as groats or flaked maize, effectively reduced magnesium intake but also improved markedly the assimilation of the magnesium present in the roughage part of the ration. An artificial roughage low in magnesium was therefore prepared from paper pulp[4]. Daily rations of wheat straw (2 lb.), paper pulp treated with liquid invert sugar (6 lb.), flaked maize (14 lb.), blood meal (3 lb.), supplementary minerals and distilled water *ad lib.* have now been offered for periods of 2–3 wk. to four lactating cows, yielding 1–3 gallons per day, and though the rations supplied a total of only 2–3 gm. magnesium daily, the serum magnesium concentrations of the cows were little affected and remained within the range 2·2–2·7 mgm./100 ml.

To determine the effect of a yet more extreme reduction in magnesium intake, a single animal was transferred, over three days, from the above ration to a highly artificial one, of wheat straw (2 lb.), casein (3 lb.), starch (14 lb.) and supplementary minerals, which provided only 0·8 gm. magnesium daily. The full ration was consumed for two days only, but during this period the serum magnesium fell from 2·2 to 0·8 mgm./100 ml. and an equally rapid recovery in concentration occurred with a return to the original ration.

An intermediate ration, of wheat straw (1 lb.), paper pulp treated with liquid invert sugar (6 lb.), flaked maize (3 lb.), casein (2 lb.), starch (4 lb.) and supplementary minerals, supplying 1·5 gm. magnesium daily, has, with two cows to which it has been offered, proved acceptable and yet effective in causing rapid falls in serum magnesium concentration. The results obtained with one of these cows to which, in addition to the above ration, occasional supplements of magnesium were given are shown in Fig. 1.

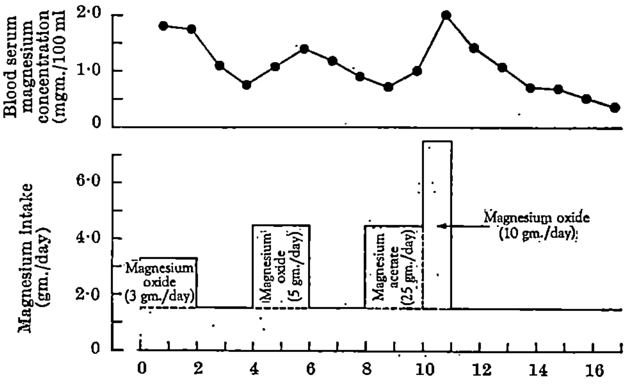

Fig. 1. Daily intakes of magnesium and the changes in the blood-serum magnesium concentration in a mature lactating cow given an artificial ration, providing 1·5 gm. magnesium daily, and occasional supplements of magnesium. (The supplement of magnesium acetate given on days 9 and 10 was not readily eaten, due to its bitter taste, and was therefore replaced by magnesium oxide. On day 17 the cow refused her food and was removed from experiment: the symptoms of tetany that can occur at a serum magnesium concentration of 0·7 mgm./100 ml. or less were not observed)

These results for a mature lactating cow show that though the net requirement for magnesium is low, the animal nevertheless depends on a continuous dietary supply for the maintenance of normal serum magnesium concentrations and at critically low levels of magnesium intake the serum magnesium concentration is rapidly affected by small changes in the intake of magnesium. They demonstrate that the freely available body reserves of magnesium must be small in relation to the requirements of a milking animal and give support to our contention[2] that hypomagnesæmia in cows at pasture is essentially nutritional in origin.

I am grateful to a number of colleagues, and in particular to Mr. V. W. Johnson, for help.

Copper in Isopods

In crustaceans the hepatopancreas is the main organ of enzyme production. In isopods this organ consists of two types of cells which differ in size and were first distinguished by Weber[1]. This author observed in the smaller cells dense clumps of yellowish granules which became the subject of some controversy. Weber thought these granules to be 'enzymogens', a contention which was denied by Frenzel[2]. Patrick[3] held the granules to represent mucin or mucigens since they could be stained—so she claimed—only with mucin stains. Patané[4], on the other hand, found the granule in question to be untouched by mucin-specific histological techniques and he considered them as catabolic products since they gave reactions characteristic of purine bases.

So far the controversial granules have been observed in terrestrial isopods and in *Ligia oceanica*, a marine isopod which leads a semi-terrestrial life. The examination of some of these animals led me to the conclusion that the nature of the granules is quite different from that assumed by previous authors.

In an X-ray spectrophotometric investigation[5] it was found that terrestrial isopods contain enormous amounts of copper—as set out in Table 1.

Of the population with the highest copper content, *Porcellio scaber* from Cornwall, several specimens were dissected and their cuticles, intestines and hepatopancreas pooled. The analyses on these samples gave the values shown in Table 2.

Table 1

Species	Source	Copper (percentage of dry weight of whole animals) (range and mean)	No. of analyses
Porcellio scaber Ltr.	Suez, Egypt	0·022–0·039 (0·032)	5
Porcellio scaber Ltr.	Vienna, Austria	0·039–0·043 (0·041)	5
Porcellio scaber Ltr.	Cornwall	0·096–0·118 (0·106)	3
Armadillidium granulatum Br.	Spain	0·047–0·088 (0·063)	4

Syspastus brevicornis Ebner	Elba	0·026–0·031 (0·028)	3

Table 2

Organ	Copper (percentage of dry weight)
Cuticle	< 0·005
Intestine + hepatopancreas	0·635
Intestine	0·076
Hepatopancreas	1·43

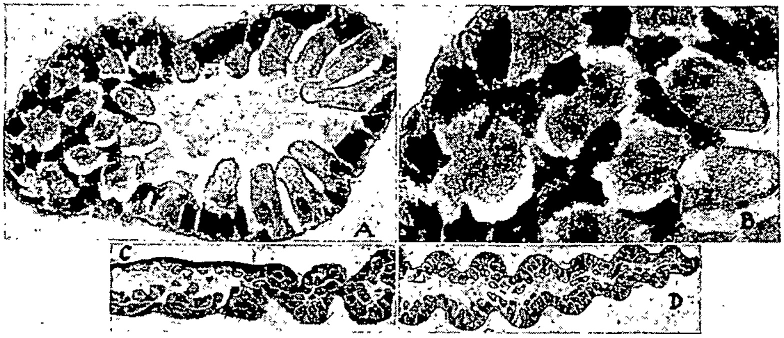

Fig. 1. Sections through one hepatopancreatic tubule of *Armadillidium granulatum* Brandt. *A,B*, transverse; *C,D*, sagittal through proximal (*C*) and distal (*D*) portion. Staining: rubeanic acid and hæm-alum. The copper appears as dense clumps of black granules

The copper content of the hepatopancreas in this species is the highest ever reported for any organ of an animal.

In sections of the hepatopancreas of *Armadillidium granulatum* stained with rubeanic acid (dithio-oximide)[6] the copper shows as dense black masses occurring intercellularly and in the small hepatopancreatic cells (Fig. 1). The large cells are free of copper which agrees with the findings of the earlier authors[1–4] that in the large cells granules do not occur. There can be scarcely any doubt that the granules observed by these authors are identical with, or contain, the copper made visible by staining with rubeanic acid.

The copper in the hepatopancreas of the animals investigated cannot be present as 'specific protein copper' since in such a state, as defined by Zuckerkandl[7], it would not react with a chelating agent like dithio-oximide. Moreover, the copper content of the hæmocyanin molecule, the cuproproteid most likely to occur in these animals, is only 0·18–0·22 per cent[8], thus even if the hepatopancreas consisted exclusively of hæmocyanin its copper content should be lower by almost one order of magnitude than it actually is. To account for its reaction with rubeanic acid the copper in the hepatopancreas of the isopods must be present in a reactive, easily dissociable state (the "cuivre naturellement réactive" of Zuckerkandl). How in this case toxicity is avoided and what the functions of these extraordinarily large amounts of copper could be remains to be investigated. Although up to now the occurrence of hæmocyanin in crustaceans has been proved only in stomatopods and decapods[9] it would not be unreasonable to expect the presence of this pigment in isopods, in which case part of the copper in the hepatopancreas might be in store for the synthesis of hæmocyanin.

All the isopods examined are reared on a diet of leaves and carrots and were kept in laboratory culture from 6 months to 6 years. Most of the isopods studied were collected and kept in culture by Prof. W. Kühnelt, whose co-operation in this investigation is gratefully acknowledged. The X-ray analyses were performed on mature, non-ovigerous, non-moulting animals in March 1961 by Dr. H. Makart at the Mineralogical Institute of the University, Vienna.

'Quick' and 'Catch' Adductor Muscles in Brachiopods

The purpose of this communication is to direct attention to the close analogy between lamellibranch molluscs and articulate brachiopods, in the structure and function of the adductor muscles. In view of the large body of work on the physiology of the adductors in lamellibranchs, it is probable that a similar study in brachiopods would yield interesting comparisons.

Like a lamellibranch shell, the shell of an articulate brachiopod consists of two valves hinged together; but brachiopod valves are placed dorsally and ventrally, are hinged on the posterior side, and have perfect bilateral symmetry. They are closed by two pairs of adductor muscles, attached separately to the dorsal valve but uniting into a single pair of tendonous attachments on the ventral valve; and they are opened not by a ligament as in lamellibranchs but by a pair of divaricator (= diductor) muscles, of which the lines of action pass behind the hinge axis (Fig. 1). The two pairs of adductors differ macroscopically in form and lustre. Microscopically, Hancock[1] noted more than a century ago that the fibres of the posterior adductors are striated and those of the anterior adductors unstriated. This observation has been doubted more recently[2], but Atkins[3] and I have been able to confirm it in several genera. The divaricators are unstriated. It has long been known that brachiopods, like lamellibranchs, snap their valves together for protection when disturbed and at other times for the ejection of pseudofæces. It has therefore seemed probable that the analogy extends further, and that the striated and unstriated adductors in brachiopods are, respectively, 'quick' and 'catch' muscles. During a recent examination of living brachiopods in New Zealand I was able to confirm this in the terebratelloids *Terebratella* (*Waltonia*) *inconspicua* (Sowerby), *T.* (*Magasella*) *sanguinea* (Leach) and *Neothyris lenticularis* (Deshayes), and in the rhynchonelloid *Tegulorhynchia* (*Notosaria*) *nigricans* (Sowerby).

When the valves snap together spontaneously, they do not close completely, and immediately afterwards begin to re-open. If the animal is disturbed (for example, by a vibration of the vessel in which it is contained), the valves snap rapidly until their edges are nearly together, and then close slowly until their edges are tightly in contact (the shell then remains closed for a variable period before re-opening). Thus both quick and slow closing movements can be distinguished in the undissected animal. If the tendonous portions of the anterior adductors are cut, leaving the posterior adductors undamaged, the valves snap together repeatedly but are unable to close tightly. If a posterior adductor is placed between a pair of electrodes connected to a stimulator, a single pulse will induce a single rapid twitch in the muscle. Thus the striated posterior adductors are clearly the muscles responsible for the rapid snapping of the valves. When an anterior part of the valve and mantle tissue is removed (making the muscles visible through the very thin anterior body-wall) the injury causes a permanent contraction of the anterior adductors, indicating that these are the muscles responsible for slow, tight and prolonged closure of the valves. The relatively slow reopening of the valves after a closure is due presumably to the contraction of the unstriated divaricators when the antagonistic contraction of the adductors has been relaxed.

The functional role of these muscular mechanisms will be described elsewhere, but it is hoped that the physiological properties of these muscles will be investigated more thoroughly by those with access to supplies of living brachiopods. This work was done at Portobello Marine Biological Station during the tenure of a Royal Society and Nuffield Foundation Commonwealth Bursary.

Paper Electrophoresis of Proteins while preserving the Pattern of their Localization in Tissues

The composition of protein mixtures extracted from different sources can be found by the usual methods of paper electrophoresis, but the localization of protein fractions in tissues can only be determined with preliminary preparative breakdown of tissues and organs.

I have now succeeded in combining these two functions by using special multilayer columns for electrophoresis made by folding and compressing one or two large sheets of paper and inserting imprints on filter paper of leaves or thin slices of animal tissues or organs. Fig. 1 shows examples of leaf-imprints obtained by a method described in refs. 1 and 2.

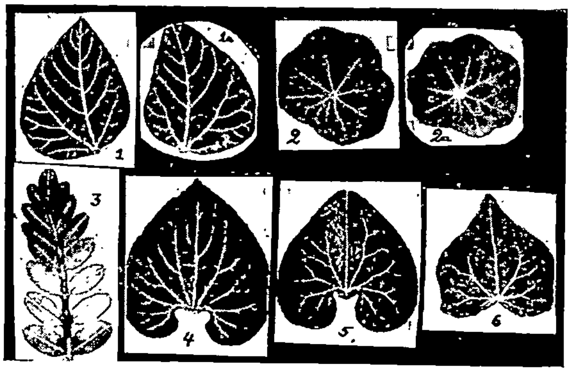

Fig. 1. Examples of leaf imprints on filter paper

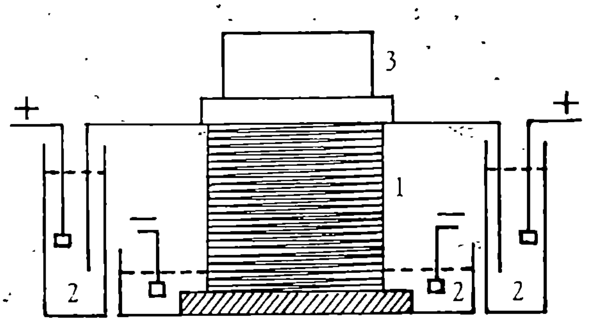

Fig. 2. Schematic diagram of electrophoresis on folded paper column. 1, Folded paper column; 2, buffer; 3, weight 1–2 kgm.

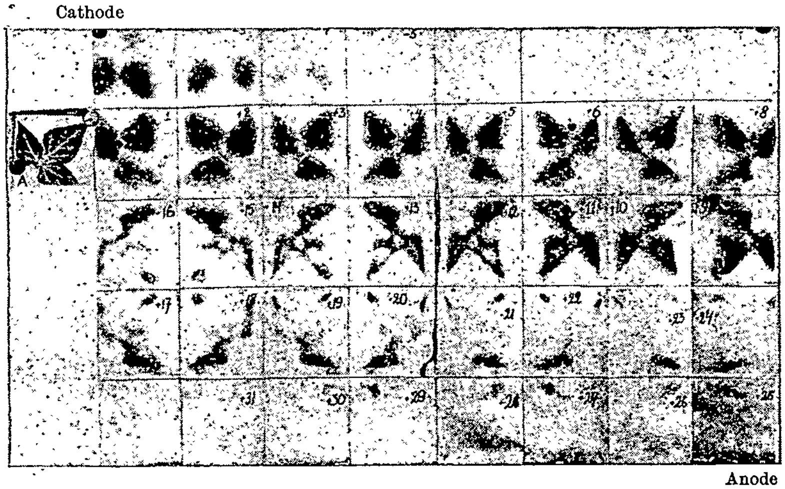

Fig. 3. An unfolded electrophoretogram of a bean leaf. Proteins are stained with bromophenol blue. Duration of electrophoresis was 2 hr. at 20 V./cm. The numbers 1, 2, 3, 4, *et seq.* indicate the sequence of layers in the folded column. *A*, the original leaf-imprint after electrophoresis. Chlorophylls and carotenoids did not migrate

Such imprints are inserted while still fresh and wet into a column of folded paper or a pile of paper disks, saturated with buffer and subjected to electrophoresis. The form of the leaf is preserved during migration of the proteins to the anode or cathode ; the localization of protein fractions may be determined by the usual methods of fixing and staining the unfolded paper electrophoretograms.

A schematic diagram of the electrophoresis is shown in Fig. 2. It is emphasized that better electrophoretograms are obtained by compressing the folded paper columns at 150–200 atm. before applying the buffer. Fig. 3 shows an electrophoretogram of a bean leaf, at the periphery of which is localized a rapidly migrating protein fraction.

This technique can probably be applied to histochemistry if materials with a finer microstructure than the usual filter paper can be used for impressing thin slices of tissues and organs. Folded, multilayer columns can of course also be used for electrophoresis of extracted mixtures of proteins.

CYTOLOGY

Fixation of Yeast Protoplasts for Electron Microscopy

In an attempt to study the plasma membrane of cells by correlation of physico-chemical experiments and electron microscopical observations, yeast protoplasts were considered as a suitable experimental material. These protoplasts are easily obtained in quantities sufficient for chemical experiments by treatment of a yeast cell suspension with gut juice of *Helix pomatia*[1–3]. In the present work *Saccharomyces carlsbergensis* strain 74 of the National Collection of Yeast Cultures, Britain, has been used.

The protoplasts are osmotically fragile, but suspended in a solution containing 10 per cent mannitol and 0·01 *M* sodium acetate–acetic acid buffer they can be kept intact at 4° C. for some days. By phase-contrast microscopy they are seen as globular bodies with a diameter of 6–7μ containing a large vacuole of about 4μ diameter and some granular inclusions (Fig. 1). Addition of 1 per cent osmium tetroxide to such a suspension for fixation causes the sudden disappearance of the vacuole and a swelling of the protoplasts to complete disintegration. This is remarkable in view of the fact that other single cells, for example, *Limnaea* eggs, ascites tumour cells and blood cells are perfectly fixed by the addition of osmium tetroxide to their suspensions. A similar phenomenon, however, was observed by Thorsson and Weibull[4] and by Lee[5] with the fixation of bacterial spheroplasts.

It was assumed that the plasma membrane of the normal yeast protoplasts is permeable to water, but not, or with difficulty, to small molecules such as mannitol and to ions. Then it was supposed that the action of osmium tetroxide on the plasma membrane renders this membrane permeable to small molecules and ions but not to macromolecules. The same suppositions were made for the vacuole wall.

Of the substances contained in the cytoplasm the most interesting in the present case are the nucleic acids and the salts.

From the dimensions of protoplast and vacuole, combined with results obtained by Eddy[6] it can be calculated that the cytoplasm contains about 4·3 per cent ribonucleic acid and deoxyribonucleic acid together, that is, about 0·12 equiv. per l. A potassium content of the same order may be derived from a table given by Cook[7] for yeast cells, whereas the sodium and chloride content is much lower, namely, about 0·007 equiv. per l. The nucleic acids will be almost fully ionized at *p*H 6, the *p*H of the cytoplasm.

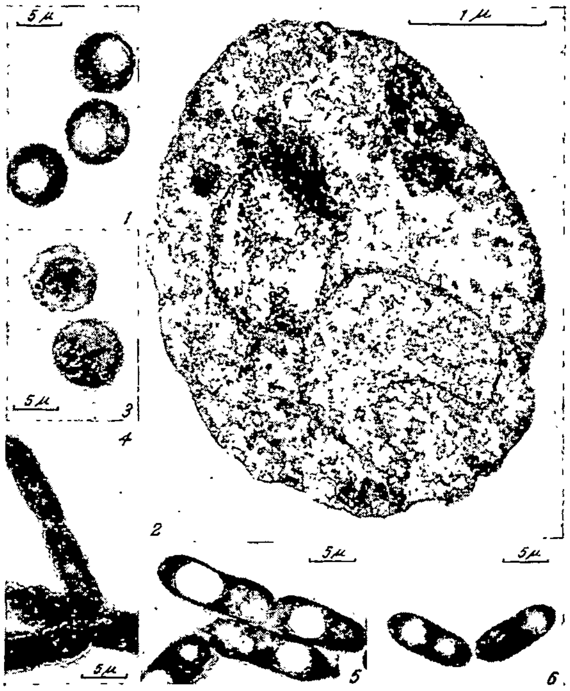
From the Donnan equilibrium, set up under the conditions which are thought to prevail after fixation, the resulting swelling pressure of the cytoplasm can be derived. This pressure is represented by the difference between the concentrations of the mobile ions inside and outside the cytoplasm. In a 10 per cent cell suspension this difference will amount to about 0·1 molar. The action of this swelling pressure leads to disintegration of the protoplast.

It proved to be impossible to counteract this swelling pressure, which makes its appearance only at fixation, by the extra addition of uncharged molecules, for example, mannitol or sucrose, to the fixation medium in order to raise its osmotic pressure.

This is in agreement with the picture given here. The effect of the swelling pressure on the protoplast will be prevented in a mechanical way by the toughness of a cell wall around the cytoplasm. In fact this is the case with normal yeast cells, which can be fixed by osmium tetroxide without disruption of the cell. The protoplasts, without such a wall, may be protected at fixation by an inversely directed Donnan effect, resulting from the addition of highly charged, non-permeating, macromolecules to the fixation fluid.

It has been found that carrageen, a sulphate colloid of equivalent weight 294, yields good results in this respect.

Fig. 2 shows an electron micrograph of a yeast protoplast fixed by osmium tetroxide at pH 5 in a solution containing 0·6 per cent calcium carragenate.



Figs. 1–6

As regards the fate of the vacuole the same line of explanation may be followed. The vacuole wall will be rendered permeable to small molecules and ions by the action of osmium tetroxide. The vacuole then collapses as a result of the swelling tendency of the cytoplasm and it does so in protoplasts as well as in normal yeast cells (Figs. 3 and 4). Fig. 5 shows unfixed normal yeast cells. As it is obviously impossible to prevent the uptake of solute by the cytoplasm out of the vacuole by the addition of highly charged macromolecules to the vacuole content, there is no issue unless the cause of the Donnan effect itself is abolished. This might be done by lowering the pH of the fixation medium to the isoelectric point of nucleic acid, assuming that the same pH will be reached in the cytoplasm.

Indeed, with fixation at pH 1·45 the vacuole of normal yeast cells does not collapse (Fig. 6).

With yeast protoplasts the picture is less clear. There is some shrinkage of the vacuole, but this may be due to an insufficient difference in diffusion-rate between osmium tetroxide and hydrochloric acid. Evidently the osmium tetroxide should arrive at the vacuole wall after the acidification of the cytoplasm, for a vacuole once collapsed will not swell again. It is feasible that the presence of a cell wall may retard the diffusion of osmium tetroxide sufficiently to this end.

The bearing of the present results on the quality of fixation of other macromolecular polyelectrolyte containing cells or isolated cell constituents seems worthy to be investigated. A more detailed report of the experiments will be submitted for publication elsewhere.

I wish to thank Dr. G. J. H. Th. Tonio for the generous supply of yeast protoplasts and Prof. J. Th. G. Overbeek for a discussion of the results.

VIROLOGY

Influence of *p*-Fluorophenylalanine on the Production of Viral Ribonucleic Acid and on the Utilizability of Viral Protein during Multiplication of Fowl Plague Virus

Experiments by Zimmermann and Schäfer[1] showed that p-fluorophenylalanine (FPA), given immediately after infection of chick embryo cells by fowl plague virus, inhibits the formation of any virus material detectable by commonly used biological methods. If FPA is given 2 hr. post-infection, the s-antigen appears normally, while no hæmagglutinin activity and no infectious particles can be detected.

With the aid of isotopic techniques two questions were explored. (1) How can the synthesis of viral ribonucleic acid (RNA) be influenced by FPA ? (2) Does the s-antigen, which is synthesized in the presence of FPA, fit into the viral particle ?

In a recent paper a method was described by which virus-specific ribonucleic acid (RNA) can be demonstrated within tissue culture cells infected with fowl plague virus[2]. The following technique was used. Phosphorus-32 was added to the culture medium. In this way only the newly synthesized RNA was labelled so that the bulk of cell-RNA could be excluded. To compare the RNA of the infected cultures with that of the non-infected ones, the RNA's were digested with RNase and the specific nucleotides and oligonucleotides were determined quantitatively. The ratios of cytidine monophosphate to oligonucleotides are characteristic for each species of RNA[3]. By the shift of the oligonucleotide pattern of the infected cells towards the pattern of purified viral RNA, one can estimate the amount of virus-RNA in the mixture with the newly built cell RNA.

In preliminary experiments it was found that the overall incorporation of phosphorus-32 into the cell-

Table 1. EFFECT OF FPA ON THE SYNTHESIS OF VIRAL RNA

Exp.	C/X	FPA 0		FPA 2		no FPA		Virus
		contr.	vir.	contr.	vir.	contr.	vir.	RNS

	AC	2·97	2·99	3·01	2·62	2·96	2·68	2·60
	GC	1·83	1·85	1·83	1·96	1·84	2·04	2·08
2	U	1·44	1·44	1·43	1·28	1·48	1·28	0·86
	AC	3·29	3·31	3·47	2·98	3·34	2·66	2·60
	GC	1·81	1·89	1·87	1·99	1·84	1·87	2·08
3	U	1·18	1·17					
	AC	2·90	2·92					
	GC	1·80	1·92					
4	U			1·66	1·51	1·70	1·50	0·86
	AC			3·33	2·96	3·75	2·88	2·60
	GC			1·82	1·90	1·89	1·82	2·08

For each sample five cultures of 24-hr.-old chick embryo cells were taken. To one group immediately after infection 270 γ/ml. FPA were added (FPA 0 vir.), to another group FPA was added 2 hr. post-infection (FPA 2 vir.). The third group received no FPA (no FPA vir.). All control cells (contr.) were not infected. In experiment 1 the cultures received 0·15 mc. phosphorus-32/culture 2 hr. post infection and were collected at 5 hr. post infection. In experiments 2 and 4, the cultures received the isotope at 4 hr. post infection, in experiment 3 at 1 hr. post infection. They were collected 2 hr. later, respectively. Only four nucleotides were determined. The ratios o cytidinemonophosphate (C) to nucleotide (X) are shown.

RNA was not affected by FPA. Particular interest was directed to the problem of whether viral RNA can be synthesized under conditions where *s*-antigen production has been stopped by FPA. If FPA is given immediately after infection, there is no difference between the RNA's of infected and non-infected cells (Table 1). Under these conditions *s*-antigen production is completely suppressed. If, however, FPA is given 2 hr. post-infection, the oligonucleotide pattern of the RNA of infected cells shifts towards that of the purified virus (compared with non-infected cells), just as in experiments in which no FPA was given.

Since FPA inhibits the synthesis of viral RNA only at early stages after infection, one may assume the formation of some kind of an 'early protein', resembling that of phages[4-6] necessary for the start of specific nucleic acid synthesis. If this hypothetical 'early protein', which is apparently not identical with the *s*-antigen, incorporates FPA instead of phenylalanine it will not be functional and synthesis of viral RNA cannot start. Once it has been synthesized normally, FPA no longer interferes with the production of either viral RNA or the material behaving serologically like *s*-antigen. Since fowl plague RNA does not contain an abnormal nucleotide[7], the 'early protein' may not be a particular enzyme, because all enzymes necessary for RNA-synthesis are already present in the non-infected cell. Its function may be to stabilize somehow the genetic information of the virus.

The assumption of a faulty 'early protein' raises the question of whether the *s*-antigen formed in the presence of FPA is identical in all respects with that produced without FPA during multiplication.

In preliminary experiments it was found that FPA had no marked influence on the incorporation of ^{14}C-leucine into normal cell proteins.

The treatment of tissue cultures with FPA was the same as that in the experiments with phosphorus-32. All cultures received ^{14}C-leucine during 2–5 hr. post infection. The incorporation of isotope was stopped by addition of large amounts of ^{12}C-leucine and virus production proceeded for another 17 hr. after removal of the FPA-block 5 hr. post-infection by phenylalanine. The virus contained in the medium was purified after addition of non-radioactive-carrier virus by adsorption on and elution from erythrocytes and was then split by ether[8]. After centrifuging to remove unsplit virus the hæmagglutinin was taken off by erythrocytes. All purification steps were followed by the determination of the biological activities in order to assure that no losses in any of the samples occurred. In each experiment all samples were treated identically.

Control cultures were grown on a ^{14}C-leucine medium prior to infection and after removal of the isotope the cells were infected. This virus yield was treated in the same way as, and compared with, virus grown at the same time in the presence of ^{14}C-leucine. The *s*-antigen of the control virus contained only 10–15 per cent of the radioactivity of that grown in the presence of ^{14}C-leucine. This radioactivity probably represents normal cell components, which cannot be separated from the virus under these conditions.

Table 2. EFFECT OF FPA ON THE INCORPORATION OF *s*-ANTIGEN INTO INTACT VIRUS

Exp.	Sample	C.p.m. in *s*-antigen	Virus yield in culture fluid HA-titre
1	FPA 0	753	128
	FPA 2	750	128
	Virus	10,000	256
2	FPA 0	211	32
	FPA 2	208	32
	Virus	2,315	64
3	FPA 2	429	128
	Virus	5,500	256

For each sample 10 cultures of chick embryo cells were infected synchronously by fowl plague virus. 270 γ/ml. FPA were added immediately after infection (FPA 0) or 2 hr. post-infection (FPA 2). The virus samples received no FPA. At 2 hr. post-infection 0·5 μM ^{14}C-leucine/culture (specific activity 6·24 mc./mM) were added to all cultures. The medium was withdrawn 5 hr. post-infection and medium containing 600 γ/ml. phenylalanine and ^{12}C-leucine 300 times in excess was added. After 17 hr. the virus was isolated from the medium by adsorption on and elution from red cells, and split by ether (ref. 8). The radioactivity was determined in the isolated *s*-antigen fraction.

The experiments shown in Table 2 demonstrate that *s*-antigen, synthesized in the presence of FPA (FPA 2) and labelled by ^{14}C-leucine, is not incorporated into the intact virus in an appreciable amount. The radioactivity in this fraction does not surpass 15 per cent of that of virus grown without FPA. The same percentage of radioactivity was found in the above-mentioned controls and in experiments in which FPA was given immediately after infection (FPA 0). Under these conditions no serologically detectable *s*-antigen is produced in the presence of ^{14}C-leucine.

It is known that FPA is incorporated into proteins instead of phenylalanine[9]. From our results we conclude that the faulty *s*-antigen, which incorporated FPA, is still serologically demonstrable but does not fit into the intact virus and therefore is excluded from incorporation into it as a viral sub-unit.

We wish to thank Prof. W. Schäfer for his interest in these experiments. This work was supported by the Deutsche Forschungsgemeinschaft.

FORTHCOMING EVENTS

Sunday, September 3—Wednesday, September 6

British Association for the Advancement of Science (at Norwich)—Continuation of 123rd Annual Meeting.

Sunday, September 3

At 11 a.m.—Service in Norwich Cathedral. Preacher: The Lord Bishop of Norwich, the Right Reverend Dr. Launcelot Fleming.

Monday, September 4

At 10 a.m.—Prof. C. F. Carter: "The Economic Use of Brains" (Presidential Address, Section F).

At 10 a.m.—Dr. K. P. Oakley: "Dating Man's Emergence" (Presidential Address, Section H).

At 11.30 a.m.—Dr. Richard G. Lipsey: "Can there be a Valid Theory of Wages?—A Study of Fact and Fiction in Economics" (Lister Lecture).

At 2.30 p.m.—Dr. Judith Milledge: "Form and Colour in Nature" (Darwin Lecture).

At 8 p.m.—Dr. B. V. Bowden: "The Impact of Automation" (Evening Discourse).

Tuesday, September 5

At 8 p.m.—Mr. Kenneth Adams: "Seeing in the Round" (*Eidophor* programme).

Sunday, September 3—Thursday, September 14

Royal Aeronautical Society; Institute of Aerospace Sciences, United States; and the Canadian Aeronautical Institute (at the Royal Aeronautical Society, 4 Hamilton Place, London, W.1)—Eighth Anglo-American Aeronautical Conference.

Wednesday, September 6—Saturday, September 16

International Federation for Documentation (in the Caxton Hall, Westminster, London, S.W.1)—27th Conference.

APPOINTMENTS VACANT

Applications are invited for the following appointments on or before the dates mentioned:

Lecturer or Assistant Lecturer in Psychology at Queen's College, Dundee—Secretary of the University, University of St. Andrews, c/o Queen's College, Dundee (September 7).

Research Assistant (graduate in science, preferably physics, with a knowledge of electronics) in the Department of Agriculture, for investigations into the measurement of radioactivity in livestock—The Registrar, The University, Leeds 2 (September 7).

Lecturer (with a degree or equivalent qualification, and teaching or other suitable experience) to teach Physics and Mathematics for Higher National Diploma Courses—The Principal, Royal Radar Establishment College of Electronics, Malvern (September 9).

Assistant Lecturer in Occupational Psychology—The Secretary, Birkbeck College (University of London), Malet Street, London, W.C.1 (September 11).

Senior Lecturer (graduate in bacteriology or dairying with considerable experience of agricultural and/or dairy bacteriology) in Bacteriology—The Secretary, West of Scotland Agricultural College, 6 Blythswood Square, Glasgow, C.2 (September 11).

Scientific Officers or Senior Scientific Officers (with a first- or second-class honours degree, preferably in science or engineering, with a wide and intelligent interest in scientific matters and aptitude for administrative work in a scientific field) in the D.S.I.R. Headquarters, London, for scientific administrative work—Establishment Office, Department of Scientific and Industrial Research, 5–11 Regent Street, London, S.W.1, quoting HQ.4 (September 16).

Technical Officer (preferably with experience in a teaching laboratory) in the Biochemistry Department, University of Melbourne, Australia, for the organization at technical level of undergraduate practical classes—The Secretary, Association of Universities of the British Commonwealth, Marlborough House, Pall Mall, London, S.W.1 (September 16).

Lecturer or Assistant Lecturer in Pure Mathematics—The Secretary, The University, Exeter (September 18).

Curator (with a B.Sc. degree with particular training in mineralogy and palæontology) of Fossils and Minerals in the Natural History Museum, Adelaide, South Australia—The Agent-General for South Australia, 50 Strand, London, W.C.2 (September 22).

Economists (2) (with a first- or second-class honours degree in economics and at least three years postgraduate experience in industry or research in industrial economics; preferably with a lively interest in technological development) in the D.S.I.R. Headquarters, Economic Section, London, to take part in planning and executing studies of the research and development needs of industries or sectors of the national economy—The Manager (PE.3324), Ministry of Labour, Professional and Executive Register, Atlantic House, Farringdon Street, London, E.C.4 (September 25).

Scientific Assistant (preferably with experience in plant nematology) to undertake the identification of helminthological collections—The Director, Commonwealth Bureau of Helminthology, The White House, 103 St. Peter's Street, St. Albans, Herts (September 30).

Chemist (with a degree in chemistry from an approved university, together with at least two years postgraduate experience, and a working knowledge of experimental statistics), to be responsible for a routine soil testing laboratory and to conduct research on tea soils and on the nutrition of the tea bush—The Director, Tea Research Institute of East Africa, P.O. Box 91, Kericho, Kenya Colony (October 1).

Lecturer (preferably with special qualifications in physiology or genetics) in Botany; and a Research Fellow (with a degree, preferably some research experience, and between the ages of 23 and 35 years) in Botany at the University of Tasmania, Australia—The Secretary, Association of Universities of the British Commonwealth (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, October 2).

Lecturers in the Department of Medical Microbiology, Makerere University College, East Africa—The Secretary, Inter-University Council for Higher Education Overseas, 29 Woburn Square, London, W.C.1 (October 4).

Chair of Chemical Pathology—The Secretary, The University, Aberdeen (October 31).

Postdoctoral Research Fellow in the Chemistry Department, for physico-chemical investigations of the surface chemistry of organic polymers of interest to the tyre industry—The Dean of Graduate Studies, University of Melbourne, Parkville, N.2, Victoria, Australia (November 30).

Assistant Biochemist, Basic grade (preferably holding the A.R.I.C., the Grad.Mem.R.I.C., or B.Sc.(Hons.) in chemistry or biochemistry), in the Group Laboratory at Crumpsall Hospital—The Hospital Administrator, Crumpsall Hospital, Manchester 8.

Assistant Lecturer, Grade B (with a good honours degree in mathematics and preferably some teaching or research experience) in Mathematics—The Clerk to the Governors, South-East Essex Technical College, Longbridge Road, Dagenham, Essex.

Assistant Professor of Biology—Head, Department of Biology, University of New Brunswick, Fredericton, N.B., Canada.

Assistant Professor of Physiology—The Dean of Medicine, University of Alberta, Edmonton, Alberta, Canada.

Biochemist (with a good honours degree and preferably postgraduate training or research experience, and interested in the use of advanced techniques, for example, high voltage electrophoresis, and in the invention of new techniques for the differentiation of bacteria), for duties which will include the supervision of a survey now in progress—The Secretary, National Institute for Research in Dairying, Shinfield, Reading, quoting Ref. 61/26.

Biometrician (with a first- or upper second-class honours degree, together with an interest in biological research, and preferably experience in agricultural experimentation) in the Department of Biometrics—The Secretary, Grassland Research Institute, Hurley, Maidenhead, Berks.

D.S.I.R. Research Assistant (graduate) in Zoology, to study the responses to environmental stress of the reticulo-endothelial system of the spleen and liver in rodents, using histochemical and enzymological techniques—Dr. L. L. de Kock, Department of Zoology, The University, Aberdeen.

Geologist (under 35, with a first- or good second-class honours degree in geology, and preferably some background of economic geology and/or a knowledge of mapping, photogeological interpretation and surveying with theodolite and aneroid barometers) in the British Solomon Islands, for geological field surveys, studies of mineral occurrences, and petrological or palæontological studies—The Director of Recruitment, Department of Technical Co-operation, Carlton House Terrace, London, S.W.1, quoting C1/RC218/18/01.

Graduate Chemist in the Soil Science Laboratory, University of Oxford, to assist research into the use of new physico-chemical techniques for assessing the availability to plants of potassium in the soil—Dr. P. H. T. Beckett, Department of Agriculture, Oxford.

Laboratory Technologist (A.I.M.L.T., and considerable experience, preferably as Chief Technician) with the Government of Tanganyika—The Crown Agents, 4 Millbank, London, S.W.1, quoting Ref. M3C/53605/NF.

Lecturer or Assistant Lecturer in Agricultural Economics; and a Lecturer or Assistant Lecturer in Farm Management in the Faculty of Agriculture (Imperial College of Tropical Agriculture), University College of The West Indies, Trinidad, West Indies—The Secretary, Inter-University Council for Higher Education Overseas, 29 Woburn Square, London, W.C.1.

Lecturer (with a good honours degree and capable of teaching physiology and pharmacology up to and including the external honours B.Pharm. degree of the University of London) in Physiology and Pharmacology in the Department of Biology—The Registrar, Leicester College of Technology and Commerce, Leicester.

Lecturer (under 45, with either A.M.I.E.E. or Higher National Diploma in Electrical Engineering, and at least three years teaching experience or relevant industrial experience), for an electrical technician's course at Kampala Technical Institute, Uganda—The Director of Recruitment, Department of Technical Co-operation, Carlton House, Terrace, London, S.W.1, quoting BCD.114/9/032/T.

Librarian (woman zoologist, age 25–35, British nationality, with a degree in zoology or biology) in an ecological library, for duties which include subject-indexing—The Director, Bureau of Animal Population, The University, Botanic Garden, Oxford.

Physicist (with a first- or second-class honours degree) in the Medical Physics Unit, to apply physics to a wide range of medical problems, initially in the radioactive isotope field—The Secretary, S.E. Regional Hospital Board, 11 Drumsheugh Gardens, Edinburgh 3.

Research Assistant (honours graduate) in Physics—The Clerk to the Governors, Woolwich Polytechnic, London, S.E.18.

Research Assistant (with a good degree in zoology and an interest in the physical and chemical properties of animal tissues) in the Study of Molecular Structure of Biological Systems in the Department of Bimolecular Structure—The Registrar, The University, Leeds 2.

Scientific Officer (with a first- or second-class honours degree in chemistry or Associate or Fellow of the Royal Institute of Chemistry, and preferably postgraduate experience in analytical work in food chemistry and insecticide analysis) in the Ministry of Commerce and Industry, Nigeria, for chemical work in connexion with the deterioration and protection of raw foodstuffs during storage in Nigeria—The Recruitment Attaché, Nigeria High Commission, 9 Northumberland Avenue, London, W.C.2, quoting Ref. E.10/2.

SENIOR LABORATORY TECHNICIAN or LABORATORY TECHNICIAN (experienced in bacteriology)—The Director, Laboratory Animals Centre, M.R.C. Laboratories, Woodmansterne Road, Carshalton, Surrey.

SENIOR LECTURERS or LECTURERS (with a first- or second-class honours degree or equivalent and preferably with teaching and/or research experience) IN MATHEMATICS, ELECTRONICS AND ENGINEERING PHYSICS—The Registrar, Royal Military College of Science, Shrivenham, Swindon, Wilts, quoting Ref. HQ.77/17.

SENIOR RESEARCH ASSISTANT (Ph.D. standard) IN PHYSICS, for a programme of work on the magnetic properties of thin films—The Principal, Royal Holloway College (University of London), Englefield Green, Surrey.

SENIOR RESEARCH FELLOW (with a university degree in science or engineering and experience in research) IN THE DEPARTMENT OF AIRCRAFT DESIGN, to engage in research in the fields of aircraft structure theory and/or solid mechanics—The Recorder, The College of Aeronautics, Cranfield, Bletchley, Bucks.

STUDENT TECHNICIAN IN THE DEPARTMENT OF PATHOLOGY, Connaught Hospital, Walthamstow, London, E.17—Secretary, Forest Group H.M.C., Langthorne Road, London, E.11.

STUDENT TECHNICIAN or TECHNICIAN (preferably with mathematics and physics at advanced level), for research work in a pulmonary physiology laboratory—The Secretary, University College Hospital Medical School, London, W.C.1.

TECHNICIAN (male or female) IN THE MICROBIOLOGICAL TEACHING LABORATORY—Mr. Edwards, The School of Pharmacy, 29–39 Brunswick Square, London, W.C.1.

UNIVERSITIES IN BRITAIN

THE vital importance of the task confronting the Robbins Committee on the educational system of Britain is being emphasized on all sides. The recent decision of the Minister of Education regarding the status of the colleges of advanced technology is admittedly only a temporary decision pending the report of that Committee, when more fundamental decisions will need to be taken regarding not simply the government and autonomy of such institutions but also their staffing, their size and their relation to the universities on one hand and to the technical colleges and technical schools on the other. The implications of their location do not appear to have been examined as they should have been, and there are also questions of staff and their status. Again, it is obvious that the expansion of the universities requires consideration both in regard to the balance, or rather the relations, between research and teaching and to the place of academic research, quantitatively as well as qualitatively, in Britain's organization for research. This is apparent from the recent report of the Council for Scientific and Industrial Research and also from the comment which has been made on the installation of the radio telescope at the Royal Radar Establishment rather than at a university. Nor can proposals for university expansion leave out of account particular problems, like that of mathematical education, to which much attention has been given recently. Even when such problems demand immediate remedial attention, any reorganization of higher education should be concerned to see that such crises do not recur.

For such reasons, Prof. H. C. Dent's little book, *Universities in Transition**, and the broadcast talks in the Third Programme by Sir Eric Ashby, "Universities To-day and To-morrow" (*Listener*, June 1), and of Mr. Norman Fisher, "The Future of Our Universities" (*Listener*, June 29), are timely. They are addressed to the layman, to the ordinary public, rather than to those who are engaged in academic work, and they should help to build up an intelligent public opinion on the issues involved in the expansion of the universities of Britain, and the implication of such expansion both for the national well-being and for the educational system as a whole. No less important, they help to place in a true perspective the numerous special issues arising out of such questions as apprenticeship and technical training generally, university selection and the content of curricula, even when they are presented in books of the quality of *The Complete Scientist* and Mr. W. D. Furneaux's Nuffield Foundation Study, *The Chosen Few*. Prof. Dent, moreover, provides an admirable select bibliography which offers the reader a reasonable conspectus of current discussion; as, in fact, in his limited field, does Mr. Furneaux.

Prof. Dent divides his space fairly evenly between the past, the present and the future. In the first section, he describes briefly what he regards as the most significant features in the development of universities in Britain up to 1939, stressing more particularly the rise of the modern universities. In the second, he outlines in some detail the expansion of universities between 1945 and 1960 and the wartime planning which made that expansion possible. Naturally, these two sections are largely recapitulation to anyone familiar with the subject, but even so, Prof. Dent contrives here and there to emphasize points that are often overlooked and bring out their relevance in the present situation, and he indicates weaknesses which we should be at pains to avoid in any future planning.

It is in his third section, when he examines critically some of the more important problems thrown up or made more acute by the present expansion, that Prof. Dent's own judgment finds free expression, and the order of priorities which he indicates deserves careful consideration. First, however, he suggests that the difficulties confronting British universities to-day can be divided, broadly, into two groups: those concerning internal administration and the conduct of university activities, and those posed by the ethos, intentions and organization of society. Most of the problems in the first group can, in any event to some extent, be solved by the action of the universities alone. None of those in the second group can.

This, of course, is a fundamental reason why it is so important that there should be a really informed public opinion as to what the universities are doing and what is involved in their expansion, although this is frequently unrecognized even by those who are foremost in pointing out that universities are social institutions. The fundamental problem, however, underlying and determining the character of all the others, Prof. Dent rightly maintains, is what kind of institution the university of to-morrow should be, or in other words: What is its primary purpose ? He agrees with Sir Eric Ashby that the social purpose of the European university has, within broad limits, remained constant throughout the ages, namely, to be society's principal means for conserving, disseminating and advancing academic knowledge, and, consequently, to be its principal source of supply of persons highly trained in academic disciplines; but he believes that in Britain the nature and scope of that purpose need reconsideration and some of its elements realignment.

Prof. Dent points out, for example, that there are now many institutions devoted solely to research, and the university is no longer the sole institution which accepts the advancement of knowledge as a corporate responsibility. Quite apart from the desirability of the colleges of technology extending their research activities, there are the independent research institutions, and it is significant that, in passing, Prof. Dent stresses the need for more co-operation and co-ordination between various institutions engaged in research. In this context, indeed, he suggests that broad fields of learning might be allocated as a special responsibility to particular institutions.

---

* *Universities in Transition*. By H. C. Dent. Pp. 176. (London: Cohen and West, Ltd., 1961.) 15s. net.

There are obvious difficulties in such an arrangement, but it may well be worth exploring, and it is interesting to note how far Prof. Dent's brief discussion is in line in a British context with the findings of a recent report of President Kennedy's Science Advisory Committee. Moreover, he accepts the impracticability of divorcing university research from teaching, and his discussion of research is designed primarily to elucidate what it is the university can offer that is unique. Even teaching at the highest level is likely, for example, to be in the future increasingly shared between the universities and other types of institution, including the colleges of technology.

Prof. Dent suggests that the answer may be found in the idea of community; not, indeed, in terms of the medieval idea, but in terms of an environment which affords, or rather compels, a wide range of academic and social experience of a particular kind. In consequence, a university must possess coherence, and the fragmentation and departmentalism which are sometimes encountered must not be ignored but removed. This fundamental question thus leads him to consider what conditions are necessary to facilitate a sense of community and the prospects that such conditions will, in fact, be accepted and satisfied.

It is not surprising to find that Prof. Dent believes that there should be a limit to the expansion of particular universities, and that he agrees with the Association of University Teachers that there should be a deliberate policy of preserving the pattern of university life found in the smaller and medium-sized universities. In consequence, he advocates the creation of new universities and university colleges, the diversion of considerable numbers of students who would otherwise enter universities into colleges of technology or technical colleges—it is not quite clear which he means—and the shedding by universities of some subjects now in their programmes. He questions outright whether purely professional subjects should any longer figure in university programmes, and suggests that at least all purely professional studies and activities should be transferred to other institutes, possibly associated with the universities after the fashion of the teaching hospitals or the teacher-training colleges, leaving the universities with the sole task of teaching the academic disciplines which are the bases of professional activities.

That is a proposal which Prof. Dent recognizes is likely to be unpopular; but it should at least stimulate some of the constructive thinking that is needed outside as well as inside the universities. If it should leave the universities with a task that is manageable in respect both of teaching and research, the considerable readjustments that professional institutions would be required to make might be well worth while. Furthermore, it would seem likely to meet some of the criticism that has been levelled at the education of the chemist and physiologist by Prof. T. L. Cottrell and Prof. J. A. B. Gray, and might offer the universities more room for adjustments in the content of studies to meet the needs of to-day and encourage breadth as well as depth in the education of scientists and technologists. At least it should give the universities the opportunity to impart something of the ideal of public service which is as essential a part of a professional code as technical competence.

Prof. Dent's next emphasis is on the quality of a student's private life. This, he rightly observes, can make or mar a student's university career, and he sees no adequate substitute for the community life of a college or hall of residence. He does not forget that there are sometimes disadvantages and defects which initiative and imagination could remove, but he challenges outright the belief that halls of residence are in general too expensive.

On the selection of students, Prof. Dent is much less detailed than Mr. Furneaux, but he is no less emphatic as to the need for some sort of clearing-house, as has now been recommended by the *ad hoc* Committee on Procedure for Admission of Students of the Committee of Vice-Chancellors and Principals, and the need for better use of school-leaving examinations and revision of procedure. He emphasizes, moreover, the importance of proper provision for the needs of overseas students, and thinks that attention to some of the factors which affect, often powerfully, the quality of a student's life might reduce the wastage and proportion of failures among those who secure admission.

This major criticism is, however, rather of the Government than of the universities. The universities cannot hope to offer their students all that a university education ought to imply without adequate financial resources. To do so, Prof. Dent observes, means something like doubling the present annual grants for recurrent expenditure, with *pro rata* increases as the number of students increases; and, no less essential, a sufficient increase in non-recurrent grants to provide adequate residential accommodation, equipment and buildings, including library as well as laboratory facilities and lecture rooms and provision for social and recreative activities. In this connexion it may be noted that Prof. P. M. S. Blackett has since expressed the concern held by many as to whether in submitting their applications to the University Grants Committee for 1962–67 the universities have made anything like sufficient provision for the cost of the scientific research which is their responsibility, the total cost of which could be about £14 million a year.

Two problems specifically mentioned by Prof. Dent in this connexion are those of specialization and breadth of education, which, as already noted, concentration on academic rather than professional disciplines might do something to ease, and the distractions from academic studies caused by sundry matters, including vacation employment. He suggests indeed that an inquiry into the entire range of university learning and teaching, including the content of syllabuses and the length of undergraduate courses, is overdue; and he points to the desirability of giving those appointed to a university academic staff who have no previous experience of teaching, particularly if young, some instruction in the arts of lecturing and handling seminar and tutorial groups, etc., in the psychology of learning and of later adolescence, the general structure of the English educational system and the rudiments of knowledge of one or two other national systems.

This is essentially an administrative matter. A second point, the relative place of research and teaching in a university teacher's life, is not, though in the first place Prof. Dent suggests that the relative load of teaching and research and the staff/student ratio should be the subject of authoritative inquiry. It is urgently necessary to-day to use the services of every university teacher to the very best advantage, and this is not possible so long as the claims of research and teaching are regarded as conflicting. Prof. Dent believes, indeed, that every member of the academic staff of a university should be constantly engaged in research, but not necessarily, nor perhaps even usually, with the idea of immediate publication; though he equally believes that the primary duty of most university teachers to-day is to teach as well as possible, and for this they must continually enrich their knowledge and understanding of their subject.

The wise distribution of a university's resources depends, of course, on the quality of its administration, but though Prof. Dent, like Sir Eric Ashby, is critical of some procedures, he does not think that any major alteration in the structure of the existing types of government would be timely. He urges some delegation of responsibility from the vice-chancellor, some relief of professors from administrative responsibilities and greater participation in academic government by members of the non-professorial staff; he also insists that it is essential to distinguish clearly between political independence and academic freedom, between the university as an institution in and of society and the methods by which that institution performs its particular and unique task. Political independence of the State the British universities no longer possess, if they ever had, but Prof. Dent does not believe that academic freedom should be limited to full responsibility for its own appointments, the organization of its courses, and the character and standards of the instruction given within a university. He is convinced that the university should also have absolute control over the admission, examination and expulsion of students; the final voice in the distribution of public funds received for recurrent expenditure; and the absolute right, subject to freely negotiated agreements, to determine what forms of research and what research projects it will undertake or approve.

All these rights Prof. Dent holds to be necessary if the university is to undertake freely, imaginatively, and flexibly its unique task which, with Sir Charles Grant Robertson, he sees as the starting point of a new renaissance, for which it creates spiritual and moral power. That belief is at the heart of his plea for ensuring that the university remains a community the members of which wrestle with the fundamental problems of life as well as pursue their intellectual tasks together, and, by and large, it seems to be accepted by Mr. Norman Fisher in his broadcast talk, when he expresses the hope that British universities of the future will live up to what was said of medieval universities by Hastings Rashdall: "Their greatest service to mankind was simply this, that they placed the administration of human affairs . . . in the hands of educated men".

Apart from this, in their broadcast talks, Sir Eric Ashby and Mr. Norman Fisher have little to say about the purpose of a university. Sir Eric is concerned chiefly with the problems which staff and students present in the proposed expansion to 170,000 places: the matter of buildings he dismisses as not an educational problem, rather more perfunctorily than Mr. Fisher approves; though it is plain enough that Sir Eric requires the existence and provision of satisfactory buildings, including halls of residence, libraries, etc., just as much as Prof. Dent or Mr. Fisher. The provision of staff of high quality he recognizes as the key problem: in his view the supply of students of high enough quality offers no difficulty, nor does he suggest that plans for university expansion in Britain will or should offer every young person capable of obtaining a first degree at a university the chance to do so. On the contrary, he points to the alternative avenues of higher education, and suggests that pressure on university places might well be relieved if teacher-training colleges and the colleges of technology were allowed to award a degree instead of a diploma.

This appears to be in line with Prof. Dent's views, as also are Sir Eric Ashby's views on research and teaching, a matter which he points out bears vitally on the problem of attracting staff of high quality. Some changes in the criteria for academic success are suggested for that reason alone. Size and location are dismissed as smaller matters, provided a university has space to be a coherent community with staff and students living, preferably, within walking distance; this again is not seriously contested by Mr. Fisher, beyond the comment that there are weighty arguments for limited size, or in any event, in big universities, a system of devolution. The question of academic government is regarded by Sir Eric as of critical importance, though he does not admit that it is necessarily a matter of size. He challenges, indeed, the existing pattern of academic organization of knowledge and suggests that some of the new universities should eschew altogether the words 'faculty' and 'department', and invent some new system even if it is too much to expect abolition of internal frontiers in the older universities. Like Prof. Dent, however, he insists that a university is a society, not a hierarchy, and that it is essential to associate the main body of university teachers with the making of academic decisions, and not leave it in the hands of some 1,200 professors. Nor does he believe that the revision of university problems is a difficult problem to solve.

Mr. Fisher has rather more to say about the purpose of a university, emphasizing the importance of a university giving its students something much more than professional skill; his suggestion for the development of graduate schools is intended to assist the university to perform its function of the transmission of knowledge as well as the extension of its frontiers, and to bridge the gaps between one specialized field of knowledge and another. He, too, sees the need for radical changes in the organization of existing universities, in recruitment of staff and in the system of promotion. By and large, Sir Eric Ashby and Mr. Fisher in their broadcast talks and Prof. Dent in his short volume provide the Robbins Committee with plenty of critical comment on important matters.

The chief task of the Robbins Committee can be described shortly as to recommend what new educational institutions are needed, what they should do and where they should be situated. The sound academic arguments for not pushing individual universities above the size of 4,000–5,000 students are apparent in these papers, and the new universities already specifically contemplated will provide some 15,000 places. A similar number may well be available in the colleges of technology, particularly if such colleges are enabled to offer a degree instead of a diploma in technology, and this might well be preferable to increasing the places in university departments of technology. Similarly, the suggestion regarding the teacher-training colleges, taken in conjunction with Prof. Dent's suggestion as to professional studies, might help. Meanwhile, however, the universities themselves should look at such matters as their degree structure in relation to catering for more general studies, the adjustment of the balance between research and teaching to the advantage of teaching, and the ways and means of meeting the residential and tutorial needs of the increasing numbers of students drawn from homes where there is no tradition of culture or reading. Whatever recommendations the Robbins Committee may make —and they should cover many institutions like technical colleges, professional institutes, and the schools themselves, as well as colleges of technology and the universities—so far as they affect the universities, it will be for the universities to decide on the methods of implementation, even if it is for the Government to will the means. The shape of at least some of the recommendations can already be forecast with confidence, and the universities should push ahead with their plans and proposals for reform and development.

HOPES OF TO-MORROW

It is disquieting that, despite all their technical skills, scientists so often have become the dupes of opportunist politicians. How adroitly Adolf Hitler manipulated them to his service. He is not the last of his species. In both halves of our polarized world scientists and technologists are to be found harnessed to the band-wagon of some capricious potentate who has succeeded in capturing the machinery of government. The Prime Minister, in his address to the Royal Society of London at the Tercentenary Banquet, claimed that politicians were the only amateurs left. Perhaps it is not too mischievous to suggest that this amateurish pursuit has incredible professional consequences. In general, scientists tend to leave their fate much to the whims of politicians. They are unconcerned with the world outside their research establishments; indeed, it is often a logical consequence of their training. To claim, as some do, that such unawareness is a virtue in itself is rather absurd.

Recently the Minister for Science raised the spectre of a languishing land, if Britain did not resort to automation more avidly*. Countries with a lower standard of living are mastering technical skills more and more. Lord Hailsham stated that, without automation, Britain will not command competitive power, but be priced out of the market. To avert this, the country must seize the lead in technology of production and be determined to remain one jump ahead of emergent countries in technical skill. He asserted that vast changes in the whole system of education would have to be made. For example, he pointed out that there are "vital questions in the field of human sciences" which are but weakly dealt with at universities and there is a dearth of management science.

It cannot be denied that new ideas in technology are necessary to prevent a mature economy from stagnating. That automation is essential for improving technology is certainly valid too. However, to suggest that national prosperity hinges on stressing automation and that education, particularly at schools and universities, be perverted to satisfy apparent technological demands of the moment is a sorry exaggeration. What may seem of paramount urgency to-day will to-morrow perhaps not seem so important.

Economic patterns are complex. A feature of a highly industrial, capitalistic economy is its sensitivity to trade-cycle fluctuations. This tendency appears to be related to the 'roundaboutness' of production; the greater the number of sequential steps between raw material and finished product, the keener is the sensitivity. Ultimately, the most powerful determinant of economic climate is what industrial and commercial management feel about the future. It is related to the temperament and emotional patterns of individuals.

To design education, particularly university education, so that scientists will acquire the skill to conjure up automatic devices to meet the expediency of the moment could, if overdone, have dire results. For example, it is possible to place too much emphasis on the type of mathematics used for obtaining solutions by electronic computation. Numerical methods on a computer usually will provide an answer, when a function is not easily integrable by analysis or say, a troublesome differential equation has to be solved. With inadequate training in analytical mathematics, the scientist will shirk an attempt at explicit solution; he will resort to a solution with a computer. The result is found speedily, but lacks the sophistication of an explicit form. The functional form of solution might have suggested startling insight into the physical significance bearing on the problem. Use of a computer tends to block such discovery.

---

* Conference on Automation and Computation, Harrogate, June 27, 1961.

Lord Hailsham's exhortations concerning problems of living, the vital questions, need to be examined. It might be well if these could be treated by using 'human science', as he suggests. But unhappily (or happily) human emotions do not lend themselves readily to rational formation. They are frankly, but fascinatingly, inconsistent. "Nature is not bound by reasonableness", as D. H. Wilkinson (professor of experimental physics at Oxford) has said. It is interesting to recall Lord Hailsham's presidential address to the Classical Association in Birmingham on April 13. There he stated that a solution to our modern perplexities, our aberrations in politics and morals, in æsthetics and philosophy probably lay in establishing again "the real validity of our moral and æsthetic value judgments symbolized in the classical culture in which we were steeped in our youth". This seems a better approach than 'human science'.

As we plan to change curricula to satisfy the technological demands of our age, let us consider likely hazards to the nation. Without knowledge of non-technological aspects of living, the adults of to-morrow will be vulnerable. They will be manipulated and beguiled. It was Stendhal who, in an article to the *Paris Monthly Review**, June 1822, wrote rather provocatively, that a really useful 'science' a man can learn is the science of knowing the motives of men's actions. When you know these, you can try to cultivate in people other motives which will lead them to act in such a way as to bring about your own happiness. It does seem that men often lie when they speak of their motives. One must try to penetrate and undermine such untruths.

The art of knowing life is acquired by involvement with the full range of human passions. One must live. Always love and hatred will move men. Personal experience sometimes teaches. There are other sources. Our literature is rich in expression, "from the whispering of affection to the raging of madness" (Nietzsche). Not from the classics alone but from the genius of those with heightened sensibility in any age is the noble art of understanding human nature to be gleaned. It is likely to be withheld from those who persistently proffer their punched programmes to our latter-day Oracle of Delphi, the computer. We need men of science who command *savoir-vivre* and who have a degree of empathy. How encouraging it is to read in *The Times* of June 28 that in the French baccalauréat examination, the entrée to universities there, respect is still shown for the irrational element. Even those candidates who plan to read science at the university might in their examinations be required to produce a dissertation on subjects such as: "What is the nature of æsthetic pleasure ?" or "Are we responsible for our passions?"

So let us not be carried away by excessive enthusiasm for the expediency of to-day, but be prepared for the demands of to-morrow. Then even while:

"Things fall apart ; the centre cannot hold,
Mere anarchy is loosed upon the World.
The Blood-dimmed tide is loosed, and everywhere
The ceremony of innocence is drowned," (W. B. Yeats)

we may have an abiding confidence to judge and judge wisely. For "a fool sees not the same tree as a wise man sees" (W. Blake).

RESPIRATORY METABOLISM IN PLANTS

Respiratory Metabolism in Plants
By Prof. Harry Beevers. (Row-Peterson Biological Monographs.) Pp. xi+232. Evanston, Ill.: Row, Peterson and Company, 1961.) 3.85 dollars.

THE title chosen for this book is meant to indicate that it does not attempt to cover the whole study of plant respiration, but is concerned only with the biochemistry of its reaction sequences. This is a rapidly developing field subject to annual inspection in various reviewing journals, but this is by no means to say that the present volume is supererogatory. It is not easy for the young student to pick the (more or less) permanent wheat from the ephemeral chaff in annual reviews. A considered statement of work from the past couple of decades is a sounder foundation, and nobody is better qualified to provide such a foundation at the present time than Prof. Beevers, who has himself made notable contributions to this work.

He has aimed at and succeeded in providing a factual statement of present knowledge with a minimum of controversy and 'interpretation' of dubious data. He covers the sequences and cycles of reactions during the production of pyruvate from glucose; the utilization of pyruvate in its various aspects, and oxidation systems and their constituent electron-transfers. These are treated at some length, and then there are briefer accounts of the energetics of respiration and the intracellular localization of respiratory enzymes.

The seventh chapter, on the regulation of respiratory-rates, seems to step a little outside the author's declared intention and to involve him rather more deeply in controversy. The remaining chapters deal with the relation of respiration to other physiological processes such as salt uptake, nitrogen metabolism, etc., and make interesting reading.

The book has been well produced in paper-back form at a price which should not put it out of the reach of its most important customers and beneficiaries—biology students. W. O. JAMES

CIVIL ENGINEERING

Civil Engineering Reference Book

Edited by J. Comrie. Second edition. Vol. 1 : Pp. xiii+518. Vol. 2 : Pp. xiii+527. Vol. 3 : Pp. xiii+599. Vol. 4 : Pp. xiii+392+lxii. (London : Butterworth and Co. (Publishers), Ltd., 1961.) £17 17s. 0d. the four volumes.

A REFERENCE book dealing with so vast a subject as the science and practice of civil engineering would assume enormous proportions if the objective was to provide a self-contained treatment of every aspect of the subject for the engineer. Its proportions would, however, be more modest if it contained a brief review of each aspect of the subject with adequate references to specialist publications. This work in four volumes, by some fifty-six contributors, appears to fall somewhere between these possible forms, though its aim (as stated in the introduction to the first edition) is to give the civil engineer a concise presentation of the fundamentals of the theory and practice of all branches of the subject.

There is a tendency, in those chapters involving mathematical analysis, to deal with matters of detail rather too briefly for the practising engineer. This is remedied in some instances by numerous references to specialist works as, for example, in the chapter on hydraulic power plants. In other instances, however, as in the chapter on strength of materials, the references given are not always adequate for the sophisticated mode of treatment adopted. (The confusion of the mathematical expressions for the strain energy and complementary energy of linear systems in this chapter is noteworthy.)

Chapters on mathematics, statistics, physics and chemistry, mechanics, mechanics of fluids, strength of materials, thin slabs and shells, surveying, building materials, cements, measuring appliances and general tables are contained in Volume 1. Volume 2 deals with soil mechanics, site investigation, foundations, hydraulic power plants (for example, dams, conduits and turbines), overhead transmission lines, tunnels and tunnelling practice, land drainage, hydraulics of rivers and canals, coastal engineering and explosives. Structural theory and practice relating to metal (including welding and welded construction), concrete, timber and brick and masonry construction, including buildings and bridges, is the subject of Volume 3. The fourth volume is concerned with waterways, highways, railways, airports, harbours and docks, water supplies, sewerage, civil engineering in town planning, works construction, specifications and quantities, fire protection of buildings, legal notes and patents (British). Extensive revision of the contents of the previous edition has been carried out, and the chapters on hydraulic power plants, overhead transmission lines, structural concrete, prestressed concrete, masonry and brickwork and aesthetics of bridge design are new.

It is surprising to find that such an important topic as the plastic theory of the ultimate load-carrying capacity of ductile metal structures is confined to a few non-mathematical paragraphs in the chapter on steel building structures, in view of the detailed treatment of many other aspects. (The chapter on the theory of structures is devoted entirely to an attempt at a comprehensive treatment of the various so-called methods of analysing frameworks in the elastic condition, and is thoroughly conventional.).

With the exception of the chapters on surveying, materials and measuring appliances and the tabulated data, the value of Volume 1 seems questionable. Almost any attempt to deal with subjects such as mathematics and mechanics adequately and in directly useful form for the engineer, within the compass of a single chapter as in this volume, would meet with very limited success. Moreover, there is no difficulty in obtaining good text-books in English on basic aspects of the engineering sciences. Works on engineering design and practice are much less common, however, and it would appear that the value of this book as a whole lies more in its presentation of this kind of matter than in the abbreviated accounts of theory which it contains. Even though a book of this kind requires fairly frequent revision (at least every ten years) to take account of progress, the appearance of a second edition is some indication of its appeal to the practising engineers for whom it is written.

T. M. CHARLTON

THE BIOLOGY OF MICRO-ORGANISMS

An Introduction to the Biology of Micro-organisms

By Lilian E. Hawker, A. H. Linton, B. F. Folkes and M. J. Carlile. Pp. 452+50 plates+48 figures. (London: Edward Arnold (Publishers), Ltd., 1960.) 35*s*. net.

THE study of micro-organisms is wide-ranging and rapidly developing. This is partly because of the increasing recognition of their economic importance as agents in the manufacture of useful products, in soil fertility, and as agents of disease and spoilage; and partly because the study of microbial physiology has much to contribute to cell physiology in general. The rapid rates of reproduction of many micro-organisms make them extremely valuable tools for the study of many phenomena of general biological importance.

There are very few books which attempt to give between one pair of covers a conspectus of the morphology, physiology and ecology of the major groups of micro-organisms. Therefore this book serves a very useful purpose as a general introduction to this wide subject, without attempting to be a complete text-book of microbiology (if such be possible). It is divided into three sections: (1) morphology and life-cycles of micro-organisms, with chapters on bacteria, fungi, protozoa and slime-moulds, algae, viruses (148 pp.); (2) physiology and metabolism (118 pp.); (3) ecology of micro-organisms, including the microbiology of soil, air and water, animal and plant pathogens, the microbiology of food and other commercial products, and industrial fermentations (140 pp.). There are an appendix (20 pp.) on some techniques used in the study of micro-organisms, and an index (26 pp.).

The book is well illustrated with many photographs and diagrams. Each chapter ends with a well-chosen list of books and articles for further reading. The book should be very useful to undergraduate students of microbiology and related fields; and to postgraduates in other sciences who wish to have in convenient form a concise survey of microbiology—of the biological forms concerned, their physiology, and the numerous fields of microbial activity. The book is well printed and well produced, and is extremely good value, by modern standards, for its modest price.

B. C. J. G. KNIGHT

WORLD-WIDE CIRCULATION OF AIR WITHIN THE STRATOSPHERE

By P. GOLDSMITH
Atomic Energy Research Establishment, Harwell
AND
F. BROWN
Atomic Weapons Research Establishment, Aldermaston

Introduction

IN 1949, Brewer[1] postulated a meridional circulation in the stratosphere to account for the low humidity measured in the lower stratosphere over southern England. At that time, the humidity measurements had been made up to heights of 42,000 ft.[2,3] using *Mosquito* aircraft of the British Meteorological Research Flight fitted with the Dobson–Brewer frost-point hygrometer[2]. These results showed that the humidity mixing ratio invariably fell rapidly with increasing height just above the tropopause. There was also some evidence, in the case of low tropopause heights, that the mixing ratio levelled off at a value of about 0·002 gm./kgm. at heights well within the stratosphere. The humidity measurements were later extended to heights of 50,000 ft. using *Canberra* aircraft[4,5]. These further data confirmed the earlier work and showed that the humidity mixing ratio steadied off at a value of about 0·002 gm./kgm., corresponding to a frost-point of about – 80° C. at 50,000 ft. This gave further support to Brewer's hypothesis that air rises through the equatorial tropopause, which acts as a cold trap since the air temperature there is about – 80° C. This dry air then moves horizontally polewards and finally sinks in the middle and high latitudes.

Dobson[6] extended this circulation model to account for seasonal variations in the total ozone over temperate and polar regions. He suggested that the cold pool over the winter pole stores ozone-enriched air which arrives by the meridional circulation from ozone-producing regions. This air subsides into the lower stratosphere of temperate latitudes in the late winter or spring and so accounts for the spring peak in the total ozone observed there.

The spring maximum of fission product fall-out from nuclear weapon tests was first attributed to the 'Dobson–Brewer' circulation by Stewart *et al.*[7]. The peaks in the fall-out distribution at temperate and high latitudes were also explained by this meridional circulation feeding the radioactive debris into the lower temperate and polar stratosphere where it becomes available for transfer into the troposphere.

However, some recent observations of the humidity and the tritium concentrations at heights of about 90,000 ft. over England[8] show that the 'Dobson–Brewer' circulation does not reach these heights. Also, Feely and Spar[9] have found that the world-wide distribution of the unique tracer tungsten-185 in the stratosphere up to 70,000 ft. is best explained by lateral turbulent mixing, rather than by large-scale meridional flow.

It is the purpose of this article to discuss these recent data and to describe a modified 'Dobson–Brewer' stratospheric model which is not only consistent with these new results but is also in accordance with other data on the distribution of radioactive debris, water vapour and ozone within the stratosphere.

Humidity Data

Measurements of the humidity of the air, the tritium content of the water vapour, the carbon-14 abundance of the carbon dioxide, together with the deuterium/hydrogen ratio of the hydrogen of the water vapour and the carbon-13/carbon-12 and oxygen-18/oxygen-16 ratios of the carbon dioxide have been made in recent years[8] at altitudes of 80,000–100,000 ft. over southern England. These measurements were made by collecting samples of the carbon dioxide and water vapour of the stratospheric air by means of a cooled vapour-trap, which was carried to these heights by balloon. From the relative amounts of water vapour and carbon dioxide collected, the humidity mixing ratio of the stratospheric air was deduced.

Table 1. HUMIDITY RESULTS ON FLIGHTS OVER SOUTHERN ENGLAND

Date	Height (ft.)	Humidity mixing ratio (gm./kgm.)
2.5.58	89,000	0·044
13.5.59	91,000	0·045
5.6.59	80,000	0·009
15.6.59	93,000	0·049
18.6.59	90,000	0·077
7.7.60	89,000	0·034
11.9.60	99,000	0·035

On the flight of 18.6.59, the balloon ascended through a thin layer of cloud, which may have resulted in water being deposited directly on to the sampling apparatus. This may account for the comparatively high humidity found on that flight.

The one measurement at 80,000 ft. on 5.6.59 is the driest (0·009 gm./kgm.) and may mean that a transition from dry air below to moist air above occurs at about this height.

It is not proposed to compare these humidity data with other measurements in great detail since this has already been done for the 1958 result[10]. However, since that publication, not only have the subsequent flights confirmed the presence of moist air above 80,000 ft., but also much independent evidence in broad agreement with these results has been accumulating. Measurements[11,12] on the infra-red spectrum of the Sun using spectrometers carried to altitudes of about 90,000 ft. by balloon have been interpreted to confirm the presence of moist air above a comparatively dry lower stratosphere. Similar measurements[13], using infra-red spectrometers borne by aircraft at heights up to 65,000 ft., lead to the same interpretation. Automatic frost-point hygrometer balloon soundings[14] up to 100,000 ft. show a similar humidity profile.

These humidity data are inconsistent with the thesis that the stratosphere above 80,000 ft. over middle latitudes receives air via a 'Dobson–Brewer' type of circulation.

Tritium Concentration

The tritium concentration of the air found over England between 1956 and 1960 using the vapour-trap technique[8] is reproduced in Fig. 1. This tritium

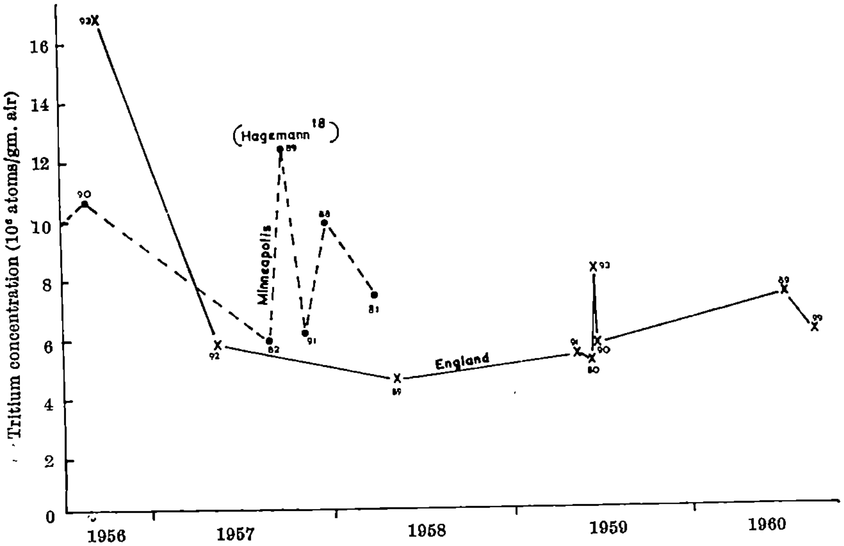

Fig. 1. Variation in the concentration of tritium above 80,000 ft.

was all contained in the hydrogen of the collected water vapour. The figures by each point give the height of the sample in thousands of feet. Also plotted are the only other comparable measurements[18] made at similar latitudes (over Minneapolis, United States) using a somewhat different technique. The bulk of this tritium has been produced during thermonuclear explosions.

Fig. 1 shows that the concentration of tritium over England since the termination of weapon testing in the autumn of 1958 has been remarkably steady and any possible large variation must have been of short duration between sampling times. The fact that the tritium concentration at 90,000 ft. has not fallen during this period suggests that the air at these heights exchanges only slowly with that at lower altitudes. This is consistent with a 'Dobson–Brewer' meridional circulation only if circulation reaching these heights is very slow. The associated humidity data, however, show that the dry circulating air does not reach 90,000 ft.

Tungsten-185

Evidence that the 'Dobson–Brewer' model is not fully compatible with the world-wide distribution in the stratosphere of late 1959 of the unique tracer tungsten-185, has recently been published by Feely and Spar[9]. The tungsten-185 was injected into the lower equatorial stratosphere at a latitude of about 12° N. during mid-1958. The maximum tungsten-185 concentration has remained at the latitude of injection near the equator above 70,000 ft., while the transfer into the lower stratosphere of higher latitudes has been quite rapid. Within one or two months of injection, tungsten-185 was found in the stratospheric debris falling out at temperate regions[15,16]. The height of maximum tungsten-185 concentration decreased progressively with increasing latitude, while the concentration compared with that at the injection latitude similarly decreased. Feely and Spar[9] suggest that lateral turbulent mixing with the possibility of some gravitational settling can best explain this tungsten-185 distribution. However, this explanation does not account fully for the observed ozone distribution, or the occurrence and maintenance of high humidities at 90,000 ft. compared with 50,000 ft.

The Requisites of a Stratospheric Model

An acceptable model of the stratosphere must be consistent with the following information pertaining to the stratosphere: (*a*) the reported world-wide distributions within the stratosphere of the following tracers: (i) tungsten-185, (ii) strontium-90, (iii) carbon-14, (iv) ozone; (*b*) the high humidities at 90,000 ft. as compared with those at 50,000 ft. in the temperate stratosphere; (*c*) the lack of a decline since 1958 in the tritium concentration in the middle stratosphere over England; (*d*) the latitudinal distribution of the radioactive fall-out of stratospheric origin reaching the ground; (*e*) the spring peak of fall-out and total ozone in temperate and polar zones; (*f*) the rapid transfer of material from the lower equatorial stratosphere to that of temperate zones, and the much greater times required for the rhodium-102 debris from rocket detonations above 100,000 ft. in the equatorial stratosphere to reach the lower extra-tropical stratosphere; (*g*) the various residence times

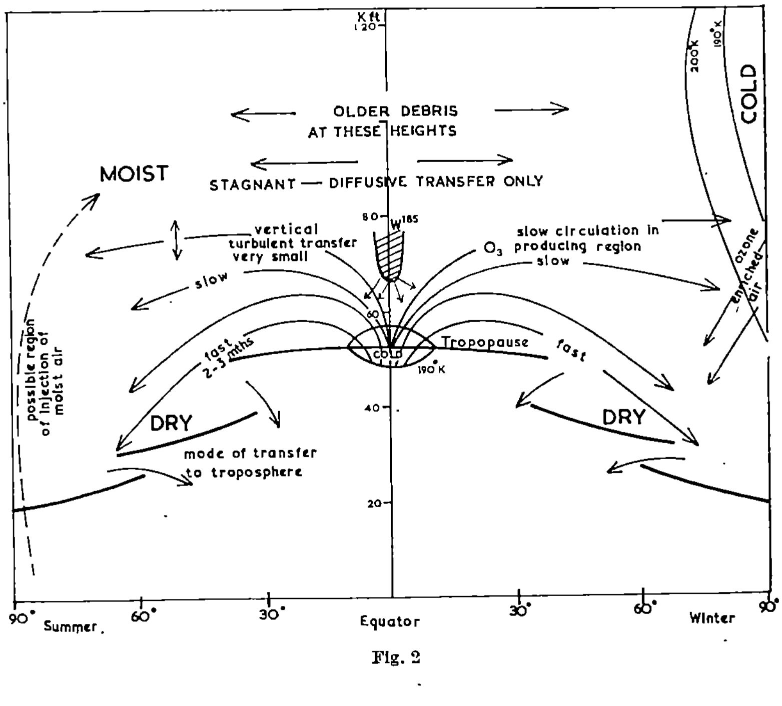

Fig. 2

of stratospheric nuclear debris depending on the latitude and height of the source.

The Proposed Model

In Fig. 2 is sketched the essentials of a model, basically the 'Dobson–Brewer' circulation with a limitation in height, which meets all the above requirements. The rising air at the equator does not reach great heights, but turns polewards almost immediately. The higher branches of this circulation reach heights of only about 70,000–80,000 ft. It is postulated that the meridional circulation is quite fast just above the tropopause, this air taking not more than two months to reach temperate zones, while the upper flow is very much slower. This slow-flowing air, therefore, stays in the ozone-producing layers for periods of about a year and slowly feeds air enriched with ozone into the polar night, where it becomes available for transfer into the lower temperate stratosphere by the 'Dobson' mechanism.

The stratosphere above about 80,000 ft. is considered to be stagnant as regards large-scale meridional and vertical air movements, and a region where small-scale turbulent diffusion may be the important means of meridional transfer. This stagnant region is moist and since the humidity gradient is probably steep in the region of the transition to the circulating air, turbulent vertical mixing must be very small, otherwise higher humidities would be observed at lower altitudes.

It is evident that some water must be lost from this stagnant region by the limited vertical mixing and during the subsidence of air from the cold pool over the winter pole. It is tentatively suggested[6] that the summer polar regions may be the sources of replacement for this water. The possibility that thermonuclear explosions themselves are the main cause of the high humidity of the middle stratosphere is considered to be unlikely. It would mean that something in the order of 4×10^9 tons of water, depending on the lateral extent of the moist layer, were lifted to these heights during the explosions. An expenditure in energy of 2,000 megatons trinitrotoluene equivalent is required to evaporate this quantity of water, that is, more than an order of magnitude greater than the published[17] energy release of all nuclear bursts over water (64 megatons equivalent).

Note added in proof. The suggestion that rising moist air over the summer polar regions may be the source of the high humidities in the middle stratosphere now appears to be doubtful. Measurements made this summer by the Meteorological Research Flight (W. T. Roach, private communication) of the frost point of the air at about 45,000 ft. at lat. 80° N., showed the air there to be dry. In view of the dry air found at all latitudes at heights of about 50,000 ft., it is difficult to see where, on the Earth's surface, the moist air of the middle stratosphere can originate. The possibility of an extra-terrestrial source, such as a high flux of low-energy protons from the Sun followed by oxidization must be given serious consideration (C. M. de Turville, *Nature*, 190, 156 (1961)).

Discussion

This model is now shown to account satisfactorily for all the broad features concerning stratospheric circulation listed above.

(*a*) (i) *Tungsten*-185: The tungsten-185 data[3] are quite consistent with the circulation pattern outlined in this article. The bulk of the tungsten-185 is in the stagnant regions, the maximum concentration therefore remaining at the injection latitude. The lower fast circulation has been provided with tungsten-185 by possible gravitational settling of the larger particles or by some turbulent mixing from above and by that part of the injection put directly into the lowest part of the equatorial stratosphere.

(ii) *Strontium*-90: The vertical distribution of strontium-90, which showed a maximum concentration above 70,000 ft. at all latitudes in 1959[9], is explained because this distribution is the result of numerous injections, since 1952, made at several northern latitudes. That part of the debris placed in the stagnant stratosphere has been spread laterally by the slow diffusion processes. The strontium-90 debris injected between the tropopause and the lower limit of the stagnant stratosphere has been carried to high latitudes by the circulation and so was in a position to transfer to the troposphere comparatively quickly.

(iii) *Carbon*-14 : The world-wide distribution in 1955 of artificially produced carbon-14 (ref. 18) similarly showed a maximum concentration above 80,000 ft. at all latitudes, with small concentrations in the lower equatorial stratosphere. This again is in full agreement with the model shown in Fig. 2.

(iv) *Ozone*: Ozone is produced naturally by photochemical action, mainly in the middle stratosphere. Sinking air in the lower stratosphere is therefore generally rich in ozone while rising air is deficient. The low ozone concentrations in the lower equatorial stratosphere[19,20] indicate rising air there. Similarly, the high concentrations in the lower temperate stratosphere during the late winter or spring[19,20] are indicative of subsiding air. The limited circulation model, like that of Dobson and Brewer, is in full agreement with these general conclusions.

(*b*) Following the subsidence of moist air from high over the winter pole during the late winter and spring, higher humidities would be expected in the lower temperate stratosphere, together with the higher ozone concentrations which account for the spring peak in the total ozone. The Meteorological Research Flight humidity measurements at 48,000 ft. over southern England do not appear, at first sight, to be in agreement with this requirement. However, it must be remembered that the aircraft frost-point hygrometer is probably not accurate to better than 2° C. when measuring frost-points of about – 80° C. There is also some evidence that it may read systematically low[21]. A study of the actual measured frost-points reported at 48,000 ft. over England[4,5] show that the humidity mixing ratio was generally 0·0015 gm./kgm., while on more than 10 per cent of occasions it was more than 0·003 gm./kgm. If a value of 0·0015 gm./kgm. were taken as the humidity mixing ratio of the air reaching the lower temperate stratosphere via the lower fast direct flow, and if 0·04 gm./kgm. as found on the balloon flights[8] were taken for that arriving from altitudes above 80,000 ft. via the polar regions, then for the actual humidity in the temperate lower stratosphere to remain within the range of uncertainty of the aircraft frost-point hygrometer, at a value of 0·003 gm./kgm., say, only about one-twentieth of the air in the lower temperate stratosphere can have come from high altitudes.

A similar calculation for the ozone concentration using the mean data on the vertical distribution given by Ramanathan and Kulkarni[19] is in good agreement with this conclusion. A value of $4{\cdot}5 \times 10^{-7}$ gm./gm.

is taken for the ozone concentration of the low direct flow, 9×10^{-6} gm./gm. is taken for that pertaining to the air at 90,000 ft., while that at 50,000 ft. over middle latitudes during the spring peak is 9×10^{-7} gm./gm. These values lead to a conclusion that one-eighteenth of the air in the latter region can have originated at 90,000 ft.

(*c*) The tritium concentrations within the middle stratosphere over England[8] show that the transfer of air from these heights to lower altitudes is slow. The replacement of tritium by lateral mixing has been at least as great as that lost by vertical transport since the termination of weapon testing in 1958.

(*d*) The explanation by Stewart *et al.*[7] of the peaks in the fall-out of radioactive material of stratospheric origin reaching the ground in temperate and polar regions[7,22,23] is still valid. The circulation has fed debris from the lower equatorial stratosphere to that of temperate latitudes where conditions are more favourable for air transfer from stratosphere to troposphere. Staley[24] has shown that conditions favourable for this transfer are not uncommon at latitudes greater than 30°. Aircraft measurements[25] of the humidity and ozone distribution in the region of discontinuities in the tropopause have demonstrated that the transfer of air from stratosphere to troposphere is particularly strong in these regions. Transport along the isentropic surfaces often passing through such tropopause gaps is probable[26].

(*e*) The smaller quantity of fall-out in the southern hemisphere[22,23] can be explained by the fact that no significant injections of nuclear debris have been made south of the equator. The material placed in the lower northern equatorial stratosphere has been quickly transferred by the circulation to higher latitudes to the north. However, that debris produced in the stagnant stratosphere would be expected to diffuse to the south as well as the north. The debris at these heights can then feed the upper arms of the circulating air of the southern hemisphere and accounts for the comparatively small amounts that have fallen there.

The spring peak in the radioactive fall-out reaching the ground[27,28] and the total ozone[6] in extratropical regions are still considered to be the result of the subsidence of air from high over the winter pole. The sudden breakdown of the winter polar vortex may be associated with the onset of this subsidence[29].

(*f*) In August 1958, rhodium-102 was placed directly into the high equatorial stratosphere at heights of more than 100,000 and 250,000 ft. in rocket detonations. This rhodium-102 first became apparent[15] in ground air at Argonne, United States (42° N.), some thirteen months after its production in the upper atmosphere. This contrasts with a delay of 1–2 months[15,16] found for tungsten-185 injected lower in the equatorial stratosphere.

Although the presence of rhodium-102 is so far unsupported by other observers, this type of behaviour for high-altitude equatorial debris, compared with that from the lower stratosphere, is to be expected on the limited circulation model. The tungsten-185 debris is in the lower fast stratospheric circulation and so is transferred to middle latitudes quickly. The onset of the rhodium-102 in the ground air occurred in September. This suggests that subsiding polar air was not the source of this rhodium-102, but that the meridionally circulating flow was the mode of transfer to the lower temperate stratosphere. The upper arms of the circulation could have received the rhodium-102 by gravitational settling and by the limited turbulent vertical mixing from above. A steady increase in the rhodium-102 for the six months following its first detection in ground air suggests that the upper circulating air may already be sinking at these latitudes.

The difference of about one year in the time required for material from the two equatorial sources to reach temperate zones indicates the order of the difference in speed between the upper and lower arms of the circulation pattern.

The work of Burton and Stewart[29] on the concentration of natural radium *D* and radium *F* in the troposphere and lower stratosphere indicates a mean circulation from low to temperate latitudes in the lower stratosphere of about six months. This agrees well with the evidence in favour of a few months for the lower flow and about a year for the higher circulation.

(*g*) The most recent estimate of less than one year[32] for the stratospheric half-residence time is considered to refer to the mean life of the debris placed in the lower equatorial stratosphere. The shorter residence time[27,31,32] for material injected at high latitudes is not surprising, since when these injections are in the lower stratosphere, they simply by-pass the meridional circulation and are in regions favourable for air transfer from stratosphere to troposphere.

Equatorial debris above 80,000 ft. will have a much longer residence time and it may be that Libby's original estimate[33] of 10 ± 5 yr. applies to this material.

It might be expected that debris resulting from high-altitude events at high latitudes would have a shorter residence time than the equivalent equatorial debris, since it is produced directly in or near those regions scavenged annually by the 'Dobson' mechanism. Its actual residence time, however, will depend on the amount of mixing taking place toward the equator in the stagnant regions of the stratosphere over polar areas.

Concluding Remarks

Murgatroyd and Singleton[34] have calculated meridional and vertical velocities in the stratosphere by considering the transfer of heat from the radiational sources to the sinks in the stratosphere. Their findings are not inconsistent with the limited circulation pattern presented here. They do indicate that above 90,000 ft., in spring and summer, there is often a region with no meridional or vertical flow, while in winter there is a slow descending circulation toward the poles. The velocities given for this meridional flow show a decrease with increasing height in the lower stratosphere. This work also shows the presence, above the stagnant region, of very strong circulations.

It is not considered that the model sketched in Fig. 2 is invariable. It may be that the height of transition between meridional circulating to meridional stagnant air is variable in time and latitude. It is possible that the spring peaks are associated with a change in the height of this boundary in the polar regions. Measurements of the humidity in the lower stratosphere directly over the poles would be of considerable interest.

It would seem that the equatorial stratosphere does act as an efficient storage reservoir of radioactive material injected there during the course of weapon testing, if those injections are made at heights greater than about 80,000 ft. Lower than this, the stratospheric circulation is very effective at transferring material from equatorial to temperate latitudes. It may be that short-lived fission products from medium-sized events at these heights add more to the fall-out reaching the ground than those from much larger injections at greater heights.

ORIGIN OF THE BRITISH INSULAR RACES OF SMALL MAMMALS AND OF THE 'LUSITANIAN' FAUNA

By G. B. CORBET

Department of Zoology, British Museum (Natural History), London, S.W.7

In the early years of this century, Hinton and Barrett-Hamilton[1] put forward a theory which asserted that the populations of Microtine rodents in the Orkney, Hebridean and Channel Islands were relict forms, once present throughout mainland Britain in post-glacial times but displaced by later arrivals from the south. These island populations were believed to be most closely related to certain forms found in the Pyrenees, Alps and in Scandinavia, which were also considered to be relict. The principal evidence supporting this theory was the morphological resemblance between the island and alpine populations, and the presence of similar forms in Late Pleistocene deposits in southern England.

A re-assessment of the problem in the light of extensive new data, both geological and zoological, suggests that the majority of these island populations are not relict, but must be attributed to introduction by human agency. The relevant geological facts, now established independently of zoological evidence[2], are that at the maximum of the last glacial phase the ice extended as far south as Norfolk and South Wales at sea-level; the rest of Britain south of the ice consisted of tundra; and the maximum eustatic lowering of the sea-level was about 70–100 metres, that is, 35–50 fathoms. As an actual depression of the shore-line, this only applies to the unglaciated south. In the north it was accompanied by a very considerable isostatic depression of the land surface so that the depression of the shore-line was very much less; and it is therefore almost certain that the Shetlands, Orkneys and Outer Hebrides have never been connected to the mainland during or since the last glacial phase.

The fossil deposits said to support the relict theory (from fissure deposits at Ightham in Kent) are now seen to represent a very long period of interstadial and late glacial time, and provide no evidence of the presence of the 'relict' types, *Microtus corneri* Hinton and *Clethrionomys kennardi* Hinton, in the post-glacial colonization.

Extensive measurements of island and mainland voles, to be published separately, have now shown that the basic characters distinguishing the island forms are very few and merely represent extremes in the ranges of variation found on the mainland. These data do suggest the presence of a relict form of *Microtus*, but not of *Clethrionomys*, on the mainland. The *Microtus* from the north-west Highlands are believed to represent a relict population, of which the distinctive features (large size and complex first upper molars) have been replaced farther south to a variable extent by interbreeding with a later arrival (*M.a.hirtus* of the relict theory). The principal dividing line seems to be the Great Glen.

Theory of Human Introduction

In the case of those islands separated from the mainland by deep channels, the geological evidence alone is sufficient to show that all the mammalian species must have been introduced; but in order to distinguish between indigenous and introduced species on the more inshore islands, we must consider also the order in which the species colonized the country, and their chances of subsequent extinction on an island. The three rodent species, *Microtus agrestis*, *Clethrionomys glareolus* and *Apodemus sylvaticus*, are

* Outer Hebrides. † Inner Hebrides.

characteristic of open grassland, scrub and closed woodland respectively. This distribution is related to their requirements of food and cover, which in turn are controlled by potential competition with each other. In northern Europe, *M. agrestis* alone occurs on the open tundra, *C. glareolus* appearing farther south, and *A. sylvaticus* yet farther south in the forest zone, whereas in Britain a similar sequence occurs in the transition from high to low altitude. It is therefore reasonable to assume that these three species would advance in the order quoted above at the time of the post-glacial colonization, with *M. agrestis* well ahead of the other species.

Many islands lack one or more of these species (Table 1). Because of their distribution by habitat, extinction due to climatic deterioration would affect *Apodemus* first and *Microtus* last. The chances of *Microtus* alone becoming extinct on any but the smallest islands are very small. The islands with which we are concerned are mostly large; for example, Lewis (870 sq. miles) and Raasay (25 sq. miles). Further, many of these islands lack the ground predators such as fox, cat, *Mustela* spp. and the adder *Vipera berus*, which are probably important enemies of *Microtus* and could conceivably cause extinction if the population was already very low.

Thus it can be postulated that the absence of *Microtus agrestis* from any large island indicates isolation since a time when the climate was severely arctic, and that any members of the fauna of the island which are characteristic of a more temperate climate must have reached the island after separation.

It is generally agreed that mice, including *Apodemus*, have been introduced by human agency; for example, to St. Kilda and Iceland. Trade among the British islands has taken place at least since mesolithic times and has involved the carriage of cattle and sheep (with accompanying fodder), building stone, timber, peat and roofing turf, all of which could have harboured voles and shrews as well as mice. Such trade is more extensive to small islands, which are deficient in natural resources, than to large ones like Ireland.

The difference of environment between mainland and island is often slight in terms of physical and botanical factors, but is vast in terms of mammalian neighbours; there are about 33 species of indigenous terrestrial mammals in northern France, 25 on the English mainland, and none on most of the islands. In particular, large size, the chief characteristic of most island forms, could have evolved rapidly due to the absence of ground predators. It is likely that the size of any species of small mammal is controlled by the interplay of opposing selective forces, intraspecific selection favouring large size, the presence of ground predators favouring small size, that is, the ability to escape into holes inaccessible to the predator. Rapid evolution would also be facilitated by the growth of a population from perhaps a single litter, allowing great possibilities of random divergence in the early stages of colonization. Examples of rapid evolution after undoubted introduction are provided by *Apodemus sylvaticus* on St. Kilda, and *Mus musculus* on North Bull Island in Dublin Bay, where a distinctive colour variety arose within a century[3].

Origin of the Individual Races

Microtus arvalis. This species is confined to Orkney and Guernsey, being absent from all the numerous western islands that are no more isolated, but are yet without *M. agrestis*. In fact there is no evidence, apart from these two cases, that it has ever occurred in the British Isles in post-glacial time. Orkney is separated from the mainland by a channel of 30–40 fathoms and its fauna as a whole suggests very early isolation. For example, there are no stoats, *Mustela erminea*. This species is widespread in the Arctic and is unlikely to have lagged behind its prey during the colonization, but equally unlikely to have become extinct on six separate islands in the continued presence of its prey. The *Microtus* themselves are absent from four large islands which are no more isolated and not separated by deeper channels than the others. Introduction from the continent of Europe could have taken place at any time since the Viking era when trade with Denmark, for example, was very extensive. Establishment would be easier in Orkney than in mainland Britain, because of the absence of competitors and ground predators.

The situation on Guernsey is similar. The absence of *M. arvalis* from all the other Channel Islands is difficult to explain on the relict theory since there is no evidence that they were isolated before Guernsey.

Microtus agrestis. The *Microtus* on the Outer Hebrides are clearly introduced since the channel separating the group from the mainland is everywhere deeper than 50 fathoms, which alone precludes contact under post-glacial conditions. Study of *M. agrestis* from the north-west Highlands of Scotland, that is, from north-west of the Great Glen, shows them to possess the complex variant of M^1 almost as universally as do the Outer Hebridean populations. It therefore seems likely that the latter have been introduced from the north-west coast.

The *Microtus* of the Inner Hebrides can be divided clearly into two groups having respectively a complex and a simple M^1 as follows: 'complex'—Skye, Eigg, Islay; 'simple'—Muck, Mull, Gigha, Arran. Those from Skye can be considered endemic since the channel is less than five fathoms deep and the fauna as a whole shows no impoverishment when compared with that

HAROLD A. SCHERAGA, *Cornell University.*

Volume 1

PROTEIN STRUCTURE

By HAROLD A. SCHERAGA

September 1961, 306 *pp.,* 64*s.*

The primary aim of this book is to present some of the quantitative aspects of the physicochemical approach to the protein structure problem, including both gross and internal structure. In discussing gross structure, polymer principles have been applied. In considering the more detailed aspects of internal structure, attention has been directed to interactions between polar groups and nonpolar ones. The material is developed from first principles, assuming only a background of elementary physical chemistry. The book has evolved from a series of lectures given for C. S. I. R. O. in Melbourne, based on research carried out in the author's laboratory during the past decade. (It will be of interest to all students and research workers engaged in the study of the structure and biological activity of proteins. It will also be of value to workers in other biological sciences in which the principles of protein structure and activity are of interest.)

Volume 2

POLYELECTROLYTE SOLUTIONS

A Theoretical Introduction

By STUART A. RICE, *University of Chicago, and*
MITSURU NAGASAWA, *Nagoya University*
With a contribution by H. MORAWETZ, *Polytechnic Institute of Brooklyn*

November 1961, 568 *pp., approx.* 115*s.*

This is the first monograph to deal exclusively with the study of the properties of solutions of polyelectrolytes. Emphasis is consistently placed on the interrelation of theory and experiment, on the construction of simple models for the interpretation, correlation, and prediction of both molecular and thermodynamic properties, and on the information derivable from the general theory of solutions without specific reference to models. The current status of our understanding of the properties of polyelectrolyte solutions is illustrated with carefully selected experimental data.

Volume 3

FLUORESCENCE ASSAY IN BIOLOGY AND MEDICINE

By SIDNEY UDENFRIEND, *National Institutes of Health, Bethesda, Maryland*

December 1961, *about* 450 *pp., approx.* 85*s.*

Besides providing a working knowledge of fluorescence theory and practice, this work is intended to convey the wide range of potential applications of this method to structural studies on proteins and other macromolecules, to research into enzyme-coenzyme-substrate interaction, to immunochemistry, to studies on endocrine secretions, and to many other areas of research and testing. "Biology" is used in a broad sense and includes applications in public health and sanitation, food inspection (including quality control), toxicology, detection of insecticide residues, and other specialized fields.

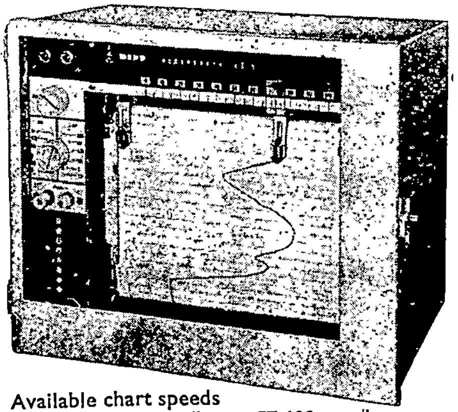
The Most Sensitive Recorder...

An instrument that records down to 50 microvolts full scale without an external amplifier

Micrograph Recorder
BD Series

This compact, ultra-sensitive Kipp Micrograph Recorder, BD Series, with 21 cm chart span, is accurate to within less than 1% of full scale deflection. Response is very rapid, full scale traverse being effected in 0.8 of a second. Up to four channels can be recorded by means of a new channel selector.

LINEARITY :
Error < 0.25% of full scale deflection
DEAD ZONE :
< 0.25% of full scale deflection



Available chart speeds range from 60 mm/hr. to 57,600 mm/hr.

Current range for full scale deflection	Voltage range for full scale deflection
0·1 μA	0·05 mV
0·25 „	0·1 „
0·5 „	0·25 „
1 „	0·5 „
2·5 „	1 „
5 „	2·5 „

of the mainland. Eigg is much more isolated (by 30–40 fathoms) with an impoverished fauna and therefore it is likely that the *Microtus* have been introduced (from the north-west Highlands). Islay, through Jura, is separated from the mainland (south of the Great Glen) by a shallow channel (5–10 fathoms) and therefore the *Microtus* population is likely to be indigenous. If so, being complex, it must be considered to be truly relict, that is, isolated before the arrival of the 'hirtus' characters. This places it in the same category as the north-west Highland form, except that in this case the isolation is complete instead of only partial. This interpretation is supported by the fact that the complex condition is more extreme and general than in any other population examined.

Muck is well isolated (30–40 fathoms) and M^1 is simple. It therefore seems likely that introduction has taken place either from the southern part of the mainland or from one of the more southern islands (for example, Mull). The *Microtus* of Mull have M^1 almost 100 per cent simple. The island is connected to the mainland on the south side of the Great Glen (through Lismore Island) by a submarine ridge 10–20 fathoms deep. It is therefore conceivable that it could have been populated before separation; but if that had been the case one would expect the population to be complex, as in the case of Islay. The most likely explanation therefore is that the *Microtus* have been introduced accidentally from the southern part of the mainland coast. The remaining islands of Gigha and Arran are probably in the same category. Arran in particular is well isolated (by 20–30 fathoms).

Microtus seem to be absent from the remaining large islands of the Inner Hebrides, namely, Raasay, Rhum, Tiree, Coll and Colonsay, some of which are no more isolated than Mull. To summarize, accidental introduction is postulated for five Inner Hebridean islands: Eigg, Muck, Mull, Gigha and Arran.

Clethrionomys glareolus. The islands of Raasay, Skomer and Jersey are similar and at the same time unique in having a large form of *Clethrionomys* with complex dentition (M^3) and no *Microtus*. The main argument in favour of accidental introduction is that *Clethrionomys* is unlikely to have colonized the country ahead of *Microtus*, but the latter is equally unlikely to have become extinct on the islands while *Clethrionomys* survived, especially in such marginal habitats to which *Microtus* is particularly well adapted. Absence of *Microtus* would favour adaptation to a grassland habitat, in particular adaptation to the tougher but more reliable and abundant food of *Microtus*. The complex dentition of these races represents a condition which is present, but in a smaller proportion of individuals, on the mainland, and the change in incidence of the complex condition could have taken place almost in one step if the colonizing parents happened to be complex. Such an occurrence in an isolated habitat on the mainland has already been recorded[4]. Once the *Clethrionomys* were established in all available habitats, subsequent colonization by *Microtus* would be considerably more difficult. The limitation of this type of *Clethrionomys* to these few islands is explained on the present theory by assuming that these were the islands on which *Clethrionomys* happened to have been introduced ahead of *Microtus*; it is inexplicable by the relict theory.

The *Clethrionomys* on Mull have not developed a complex dentition presumably because they were confined to their normal ecological niche by the prior presence of *Microtus*. If it is accepted that the latter have been accidentally introduced, as argued above, then the same must be said of the *Clethrionomys*.

Apodemus sylvaticus. *Apodemus* is more likely than the voles to be transported accidentally and at the same time is likely to have been a late, woodland colonizer. Its survival on small treeless islands does not contradict this, since there it is free from competition from voles. It is therefore postulated that all the following populations of *Apodemus* have arisen by accidental introduction: Shetland, Orkney, Outer Hebrides, all Inner Hebrides except Bute, Ireland, Isle of Man, Scillies and Channel Islands.

Sorex minutus. This species is very widespread on the islands and seems likely to be indigenous on many of them. This is not unexpected since its present range, extending to an altitude of more than 4,000 ft. in Scotland, suggests that it may well have been in the forefront of the post-glacial colonization. Introduction need only be postulated for Orkney, the Outer Hebrides and perhaps some of the more isolated Inner Hebrides. The presence of *S. minutus* in Ireland could be explained by early post-glacial entry from Scotland, but survival in the south of Ireland during the last glacial phase cannot be ruled out, nor can introduction.

Sorex araneus. From its distribution and present habitat this species appears to have been slightly in advance of *M. agrestis* in its post-glacial spread. Most of the small islands on which it occurs are not deeply separated from the mainland and therefore on these it may be indigenous (Raasay, Skye, Mull, Islay, Jura, Gigha, Bute, Skomer). It is only present on a very small proportion of the more isolated islands (Arran, Jersey) on which it was probably introduced.

Crocidura spp. This genus is present only on the Scilly and Channel Islands. It has a much more southern distribution than any of the others dealt with and is thus likely to have been a late colonizer. It is therefore considered to have been introduced on all these islands. The ubiquity of *C. suaveolens* on the Scilly group has been used as an argument against chance introduction[5]. But its usual habitat, among the kelp on the storm beaches, coupled with the extensive use made of the kelp for manure and reduction to ash, suggest clearly how it could have been distributed among the islands.

Origin of the Irish Fauna

The so-called 'Lusitanian element' in south-west Ireland has been a stumbling-block to all students of the history of the British fauna and flora. Recent authors have been forced to postulate glacial survival on land now submerged off south-west Ireland[6], or very early post-glacial colonization by land[7]. We may ask first why a land link should have allowed passage of such a non-athletic creature as the slug *Geomalacus maculosus*, which typifies the Lusitanian element, and not of such vertebrates as rodents and reptiles which abound in Iberia ? Alternatively, it is inconceivable that the vertebrates but not the invertebrates should have perished in a glacial re-advance. The present distribution of the Lusitanian species, confined to the warmest corner of Ireland, scarcely suggests great tolerance of peri-glacial conditions. On the other hand, trade between Iberia and Ireland has taken place since mesolithic times, and the size and habits of the Lusitanian species predispose them to such a form of transport.

The Lusitanian flora has probably had a similar origin, but in this case there is the additional possibility of carriage by birds which could have taken place at any time in the post-glacial period, Ireland and Iberia lying on a major migration route. In a recent survey of the botanical problem, Godwin[8], who dismisses glacial survival but accepts the idea of early post-glacial colonization by land, lists only one Lusitanian species from an early post-glacial horizon, namely, *Erica mackaiana* from the Atlantic period. This is a species which could easily have been carried by birds.

The absence of some of these species from the climatically similar south-west of England is to be expected, since there they would meet competition from related, indigeneus species which are absent from Ireland (or have only been introduced later from England).

The Irish fauna as a whole is of such an erratic composition as to suggest a series of chance introductions rather than an orderly sequence of arctic, followed by more temperate, faunas, until at some stage the supply has suddenly stopped due to severance of the land connexion. The absence of voles suggests that the last connexion (to Scotland) was severed at a very early climatic stage. However, a narrow channel or wide river would effectively bar small mammals while allowing unrestricted passage to many insects, birds and plants. Thus a south-flowing river could have allowed such selective colonization in the southern Irish Sea region while a truly terrestrial bridge in the north was inaccessible to most species because of the climatic severity.

THE DEVELOPMENT OF THE NEON GLOW LAMP (1911-61)

By PROF. H. E. WATSON
Emeritus Professor of Chemical Engineering, University of London

FOR ten years after its discovery (1898), the world's supply of pure neon was contained in two small tubes inverted over mercury which stood on Sir William Ramsay's mantelpiece, and experiments on its use as a commercial illuminant were scarcely to be expected. In 1908, however, Georges Claude designed an extra stage for his oxygen plant and produced, hourly, 12 litres of a gas containing 45 per cent of mixed helium and neon. While purifying some of this gas in Ramsay's laboratory, I noticed the great ease with which neon conducted the electrical discharge, and, two years later, working in the Cavendish Laboratory, I found that the cathode fall with aluminium electrodes in pure neon was 200 V. This indicated that, provided conditions were such that there was no positive column, a lamp would operate at approximately this voltage. Further measurements of the spark-potential confirmed this, and several experimental lamps were made, some of which would start with 150 V. and run at 85 V. The important feature of all of them was operation on the domestic voltage of 220, although in France and the United States, where the usual value was 110 V., they were not of great interest. A provisional patent was applied for in March 1911, but was not completed as I had to abandon this work on taking up an appointment abroad. These lamps, in which substantially the whole of the light comes from the negative glow, are known as 'glow lamps', or familiarly in recent years 'neons', and a useful property is that the glow follows the shape of the cathode and can thus be used for illuminated signs. In the long, tubular, high-voltage neon lights, the illumination comes from the positive column. These were first shown in public by Claude in 1910.

Experimental glow lamps were made by Dr. D. McF. Moore in the General Electric Laboratories, in Schenectady, from 1914 onwards, but even by 1920 no reliable lamp had been produced which worked on 110 V., and it was decided that this type of illuminant was of no great value. In Germany, on the other hand, the firm of Pintsch A.G. realized that although the efficiency of glow lamps, normally an important criterion, was low, there were many more uses than appeared at first sight. The smallest filament lamps for 220 V. then made were 15 candle-power, taking 20 W., and these were very expensive and fragile; in many cases, such as for nightlights and in mines, they could be replaced advantageously by 3-5 W. glow lamps. These were also valuable as indicators on switchboards. In consequence, their research department, under Dr. F. Schröter, undertook extensive investigations during the War, and in 1918 produced the first commercial glow lamps. These resembled filament lamps in size and were suitable for 220 V. In 1920 Osram G.m.b.H were making similar lamps designed by Dr. F. Skaupy at the rate of 500 a day.

It must be remembered that at that time very little was known about the mechanism of the discharge and that practically all the experimental work was empirical. The early lamps suffered from sputtering of the electrodes, which blackened the tube and absorbed the gas, sometimes in a few hours, while the methods of evacuation and removal of gases from the walls of the tube would now be considered crude. Troubles due to these causes had been met with and largely overcome by Claude and other makers of high-voltage tubes, but their remedies were not all suitable for the production of small lamps in quantity, and much new work became necessary. Freedom from diatomic gases had always been considered essential for preserving the colour of the discharge and obtaining the minimum spark-potential until Pintsch A.G. in 1917 showed that very small quantities of these gases not only did not affect the colour but also lowered the spark potential and reduced sputtering to a quite unexpected degree. Shortly afterwards, N.V. Philips recommended a helium–neon mixture containing up to 5 per cent of argon for the reduction of sputtering, and in 1926, T. E. Foulke at Schenectady, with far more theoretical knowledge at his disposal and after prolonged investigations, confirmed the value of a mixture of this nature.

Meanwhile, efforts were being made to find materials with a low cathode fall which would enable glow lamps to start and run on 110 V. d.c. Skaupy solved this problem in 1917 by coating metallic electrodes with barium azide and afterwards heating them, but simplification and improvement of the process took nearly five years. N.V. Philips in 1921 made tubes with cathodes of magnesium and beryllium alloys which would start below 110 V. and obtained improved results by introducing potassium nitrate. These results aroused great interest in the United States, where Foulke had been studying the effect of gas composition, as mentioned above. He soon succeeded in producing a tube with magnesium electrodes which would start with 70 V., and three years later he had developed two new coating processes now known as the 'oxide' and the 'azide'. The first started with barium carbonate, which was heated in the tube to 1,000° C. or more and activated by a discharge with a steep-fronted wave-form. The second was similar to Skaupy's but a little cæsium was added to the barium and the subsequent processes were strictly controlled. The result was a lamp starting with 45 V. a.c.

During this work, an outstanding design of lamp was evolved. The lamps, named *T*-lamps, were made from tubing ¼-in. or less in diameter, with two parallel wires as electrodes, the overall length being less than 1 in. These miniature lamps, bright enough to be seen as indicators and readily incorporated in instruments, caused an increased demand, but it was not until about 12 years ago in the United States and a few years later in Britain that a remarkable development took place, caused by the introduction of glow lamps into domestic appliances such as electric irons and refrigerators, and later into switches. The demand was far greater than had been foreseen and much ingenuity had to be exercised in developing machinery to carry out what was still a highly complicated process requiring the greatest precision. It is estimated that the world output of neon glow lamps is now about 80 million a year, and is increasing rapidly. Quite 80 per cent of these are of the *T* type. These can be sold for less than a shilling, are remarkably robust and reliable, and will run for their rated life of 25,000 hr. at a cost of twopence.

Within the past few years a demand has arisen for 'high brightness' lamps which can be seen readily in full daylight. This could not be met by minor modifications of existing processes and required a great deal of additional research, one item being a study of lanthanum and its alloys. Satisfactory lamps are now in production in several countries, but research is by no means at an end.

These notes are extracted from a longer account of the development which I have compiled, and it may be mentioned that a very valuable publication has just appeared dealing with the scientific basis of the glow discharge, with 156 references, written by M. P. Lemaigre-Voreaux as a D. ès Sc. thesis presented to the University of Lyons.

OBITUARIES

The Right Hon. the Lord McGowan, K.B.E.

LORD MCGOWAN OF ARDEER, who died on July 13, was honorary president of Imperial Chemical Industries, Ltd., of which he was chairman from 1930 until the end of 1950 and for the creation of which, with Sir Alfred Mond, afterwards Lord Melchett, he was mainly responsible.

Henry Duncan McGowan was born in Glasgow on June 3, 1874, and educated at Allan Glen's School, entering the Glasgow offices of the Nobel's Explosives Co. in 1889 as a junior clerk or office boy. He became assistant successively to the home and to the overseas sales manager, and then, in 1902, deputy assistant sales manager, and in 1909 assistant manager. In December 1915 he was appointed to the board and became primarily responsible for co-ordinating the Company's activities in relation to the requirements of the Ministry of Munitions. In 1918 he was appointed managing director, and in recognition of his services during the War he was created K.B.E. At the conclusion of the War he was responsible for the merger of all the important explosives and ammunition companies in Britain into Explosives Trades, Ltd., of which he became chairman and managing director. Earlier, in 1910, he had used the Hamilton Powder Co. as a nucleus for the amalgamation with three other explosives companies and the Dominion Cartridge Company of Quebec to form Canadian Explosives, Ltd., and in the winter of 1923–24 he also negotiated the formation of African Explosives and Industries, Ltd., in South Africa.

The creation in 1926 of Imperial Chemical Industries, Ltd., by the joint efforts of McGowan and Sir Alfred Mond, out of Nobel Industries, Ltd., Brunner Mond and Co., Ltd., the United Alkali Co., Ltd., and the British Dyestuffs, Ltd., was thus the crowning of his persistent efforts towards amalgamation and rationalization of the chemical industry of Britain, and McGowan became president and Mond chairman of the new Company. Mond (afterwards Lord Melchett), however, died in 1930, and McGowan succeeded him as chairman, and the growth and shaping of the enterprise were very largely his work. By 1938, however, he realized that it had become too large to be managed efficiently from the centre and that the advantages of large-scale production were in danger of being offset by rigidity, and McGowan initiated some degree of decentralization.

By temperament McGowan was something of an autocrat, but he was a good mixer and, working hard and thoroughly himself, he expected the same of others. What mattered was the way the job was done, and with marked ability to grasp the essentials of a problem, he was also swift to see and seize an opportunity. Melchett had been elected president of the Society of Chemical Industry in 1930 in view of the Society's jubilee meeting in London in the following year. On Melchett's death McGowan took his place, and his presidential address to the Society on "Science and Industry" in July 1931, and his Messel Memorial Lecture to the same Society at Cardiff three years later on "The Uneven Front of Research" display very fairly his outlook on science and technology.

He was created a baron in 1937 and received honorary degrees from the Universities of Glasgow (1934), Birmingham, Oxford, Durham and St. Andrews. He married in 1903, Jean Boyle Young, of Paisley, who died in 1952, and he is survived by two sons and two daughters, the title passing to his elder son, Harry Wilson McGowan.

R. BRIGHTMAN

Sir Hugh Warren

HENRY WILLIAM HUGH WARREN was born on June 30, 1891, and died on June 18, 1961. He is survived by Lady Warren and a daughter. An only son was killed serving with the R.A.F. in 1939.

Hugh Warren, in 1929, took over the Research Laboratory at the British Thomson-Houston Co., Ltd., Rugby, which, six years previously, he had helped the late R. C. Clinker to start. In 1938 he was appointed to the board of B.T.H. as director of research. He remained in charge of the Laboratory until 1945, becoming managing director of B.T.H. in that year and managing director of A.E.I., Ltd., in 1948, retiring in 1954. He received honorary degrees from the University of Bristol in 1942 and from Birmingham in 1946, and was knighted in 1951.

It is as leader of what is now the A.E.I. Research Laboratory, Rugby, a job he did for sixteen years, that 'H. W.' will be remembered. He was alert and interested in everything, intensely energetic and always desirous of presenting the work of his Laboratory in as impressive a manner as possible. His own subject was insulations. It was in 1916, on the then vital matter of the insulation of magnetos, that he showed the energy and enthusiasm to engage in, and pursue relentlessly, difficult technological problems that proved to be characteristic of the man. He directed with vigour the pioneer work of his Laboratory on sound reproduction, talking films and discharge lamps. During the War, starting with the *VFO* ('Valve for Oliphant') klystron, he built up a large effort on centimetric radar, including work on magnetrons and other microwave valves, radar sets and the silicon and germanium crystal valves which were the forerunners of the modern semiconductor devices.

He played a part of considerable significance in bringing about cordial and fruitful co-operation between teams of scientists from industry and those from Government and military establishments that frequently met together at Rugby to attempt to solve some of the problems of the times. Such meetings were memorable and, whether 'H. W.' took the chair or not, his presence with its sense of urgency and promise of achievement helped us all to accomplish things that seemed to border on the impossible. He enjoyed overcoming the difficulties of people as well as those of physics and production.

Hugh Warren was a member of many engineering institutions, councils and committees, and was the author of many technical papers and a comprehensive volume published in 1931 entitled *Electrical Insulating Materials*.

He loved writing, and would spend odd minutes as well as long hours on semi-technical essays, some of which were gathered together in a volume called *ON—Some Irresponsible Jottings, Scientific and Otherwise*, published for private circulation in 1944. He had a great sense of humour and was a pleasant companion and a kindly and courteous leader; he will be remembered with admiration and affection.

L. J. DAVIES

NEWS and VIEWS

Technical Managing Director of Reactor Centrum Nederland: J. Pelser

JOHANNES PELSER has been appointed technical managing director of the Reactor Centrum Nederland foundation in succession to J. J. van Rijsinge. Johannes Pelser was born at Dordrecht on March 21, 1925, and matriculated at the Christian Grammar School at Dordrecht; afterwards he studied at the Technical University at Delft, where he obtained his certificate for physical engineering in 1951. Following this he joined the Foundation for Fundamental Research on Matter, but was transferred to the Reactor Centrum Nederland foundation when it came into existence in 1955. While at the Foundation for Fundamental Research on Matter, he was seconded to the (Netherlands–Norwegian) Joint Establishment for Nuclear Energy Research at Kjeller, Norway. Here he worked for four years and took part in the research work with the nuclear reactor *Jeep*. A short time after the setting up of the Reactor Centrum Nederland, Pelser returned to the Netherlands and took an active part in the preparations for the building of a research centre at Petten. In 1957 he was sent to the United States as a representative of the Reactor Centrum Nederland to supervise the fabrication of the high-flux reactor. By the end of 1958 he was appointed head of the Reactor Department at Petten, taking charge of the preparation and experiments with, and the operation and maintenance of, not only the low-flux reactor but also the high-flux reactor.

Aircraft Propulsion at the College of Aeronautics, Cranfield: Prof. A. H. Lefebvre

PROF. A. H. LEFEBVRE has been appointed to the chair of aircraft propulsion at the College of Aeronautics, Cranfield, in succession to Prof. A. G. Smith, who is now head of the Mechanical Engineering Department, University of Nottingham (see *Nature*, 187, 743; 1960). After leaving Long Eaton Grammar School, Prof. Lefebvre served an apprenticeship at Ericssons Telephones, Ltd., where he was employed afterwards for several years on engineering production and inspection. He studied electrical engineering at Loughborough College and mechanical engineering at the University of Nottingham. He is a graduate of the University of London and a postgraduate student of the Imperial College of Science and Technology. Since 1952, Prof. Lefebvre has been with the Aero-Engine Division of Rolls-Royce, Ltd., where his main responsibilities have been in combustion research and in the design and performance analysis of gas turbine combustion systems. He is the author or co-author of several published papers on combustion and heat transfer, and is the United Kingdom editor of the new review series, *Progress in Combustion and Propulsion Science and Technology.* Until recently he was a member of the Combustion and Propulsion Panel of the Advisory Group for Aeronautical Research and Development of NATO, in which capacity he contributed as author and editor to several publications of the Advisory Group for Aeronautical Research and Development.

Photography at the Federal Technical College, Zurich : Prof. W. F. Berg

Dr. W. F. Berg has been appointed professor of the Photographic Institute of the Federal Technical College in Zurich, in succession to Prof. J. Eggert. Dr. Berg has already established an outstanding position as an authority on scientific aspects of photography. He started research work at the early age of sixteen in the X-ray laboratories of Siemens in Berlin under his father, Otto Berg, and graduated Dr. phil. of Berlin in 1932. The activities of the Nazis brought him to the University of Manchester in 1933, where he studied the growth of crystals, for which he was awarded a Ph.D. degree in 1936. In the same year he joined the Research Laboratories of Kodak, Ltd., where he soon began work on the fundamental processes in the formation of the photographic latent image. This work, on the temperature coefficient of sensitivity and the time required for build-up of the latent image, gave results in complete agreement with the theory of Gurney and Mott that the formation of the latest image was a two-stage process, and had much to do with the general acceptance of that theory. This work was followed by other investigations of the photographic process, less spectacular in their impact maybe, but not less important. This work was recognized by the award of a D.Sc. (Manchester) degree. For about a dozen years Dr. Berg has been in charge of aspects of research into photographic emulsions of more immediate practical application. His present appointment is a not unnatural result, not only of his authoritative position in photographic research work but also of his interest in education. He has been interested for many years in education in medical photography and is a member of the Education Committee of the Institute of British Photographers.

Editor of *Discovery* : Mr. Gerald Leach

Gerald Adrian Leach was recently appointed to the editorship of *Discovery.* Born in Colombo in 1933, Mr. Leach was educated at Glengorse School and Dauntsey's. He read for the Natural Sciences Tripos at Clare College, Cambridge, taking Part 1 in 1954, in physics, mathematics, geology and mineralogy, and Part 2 in 1955, in geology. Since Cambridge, he has been a full-time science writer and producer. In 1957 he worked on the *Manchester Guardian* as a general reporter and assistant to the Science Correspondent, and the following year was script-writer for scientific documentary films with the Film Producers Guild. In 1959 he wrote and presented 35 programmes in the Associated Television science series, "It Can Happen To-morrow". In October that year he joined the BBC Television Outside Broadcasts Department as assistant producer on the 1960 "Eye on Research" television series. In 1960 and early this year he helped to plan, and write the scripts for, Dr. Bronowski's series, "Insight".

British Association for the Advancement of Science

The annual report for 1960–61 of the Council of the British Association to the General Committee characterizes the year as one of major expansion with a total audience of 140,000, or nearly double that of any previous year, and a rapid growth in the demand for lectures and other forms of presentation of science (Pp. 31. London: British Association for the Advancement of Science, 1961). Three new Area Committees were established during the year, making a total of sixteen, and the Junior British Association meetings continued to expand, while an entirely new type of meeting was the science fair held in Manchester in March 1961. A grant of £6,000 from the Leverhulme Trust Fund enabled a research project for the study of the generating of mathematical insights to be initiated under Dr. Z. P. Dienes, and the work of the Unit is to last two years. During the year, films have been shown to audiences totalling 78,000 and other visual aids to audiences totalling 10,000. Some twelve receptions were organized, at which science teachers were shown a programme of films and other visual aids display. A survey of the use of visual aids by science teachers in schools in Essex was reported in *The Advancement of Science* for September 1960 and a more detailed report of the survey was in subsequent issues of the *Film User.* Following the Cardiff meeting, eight research committees were appointed on the recommendations of various sections and grants were made to three of these.

Successful Operation of *Nimrod* Injector

On August 1 the first proton beam accelerated to the design energy of 15 MeV. was obtained from the linear-accelerator injector which forms the first stage of *Nimrod,* the 7,000-MeV. proton synchrotron under construction at the Rutherford High-Energy Laboratory of the National Institute for Research in Nuclear Science, Harwell. The linear accelerator consists of a cylindrical copper cavity approximately 44 ft. long and 5·5 ft. in diameter, with 48 drift tubes spaced along its axis, the whole being enclosed in a vacuum envelope. Approximately 1 MW. of radio-frequency power is supplied to the cavity at its resonant frequency of 115 Mc./s. to set up the required accelerating fields across the gaps between drift tubes. The function of the drift tubes is to screen the protons from the field when its direction reverses every alternate half-cycle, and they also contain focusing magnets which constrain the protons to form a proper beam close to the machine axis. The drift tubes increase in length along the tank to correspond with the increase in proton velocity. Protons enter the linear accelerator with an initial energy of 0·6 MeV. from a pre-injection stage which is basically a conventional d.c. accelerator. Pulsed 15-MeV. beams will be delivered by the injector to the synchrotron at rates up to 2 per sec. and at pulse lengths up to 2 m.sec. Within the synchrotron, they will be constrained to a circular path by a suitably varying magnetic field. In this way they will make many revolutions, receiving a small acceleration at a particular point in the orbit until the output energy of 7,000 MeV. is reached. Construction work on *Nimrod* started in August 1957 and is expected to be completed during 1962.

Aeronautical Research in Asia and Africa

The International Civil Aviation Organization is to participate with the Governments of India, Morocco, Thailand and the United Arab Republic in setting up and operating an aeronautical research laboratory and three civil aviation training centres. The laboratory is to be at Bangalore, India, where an Aeronautics Department in the Indian Institute of Science already exists. The prime objective will be the investigation of flight problems related to the design, construction and operation of aircraft in India. The laboratory will also undertake research and development work in allied fields of importance in India's economy, such as wind power and industrial aerodynamics.

The three new civil aviation training centres are to be in Morocco, Thailand and Cairo (U.A.R.). All three aim to train personnel in aircraft maintenance and operation to the recognized International Civil Aviation Organization standard. These centres will be open to trainees of neighbouring countries. Thus, the Moroccan centre in association with a similar Tunisian establishment will serve other African countries; Thailand will cater for south-east Asia; and Cairo will be the centre for the Middle East. In addition, the International Civil Aviation Organization is to help the centre already operating in Mexico City to increase its capacity and raise the level of training. In this way it is hoped that the supply and standard of trained civil aviation personnel throughout the world may be satisfactorily increased and improved to meet the increasing demand from the still expanding field of air transport. The Governments concerned and the United Nations Special Fund will provide the necessary financial support. The International Civil Aviation Organization will administer the scheme and provide any necessary additional funds.

Sterilizing Materials for Hospitals

ALL new hospitals in the United Kingdom will include a central sterile supply department, and many existing hospitals are already planning or constructing such departments. A small book, edited by Brian Watkin, assistant editor of *The Nursing Times*, describes the experience which has already been gained in setting up central sterile supply departments (Pp. 58. London: Macmillan and Co., Ltd., 1961. 4*s.* 6*d.*). Such departments have not only produced considerable financial economies but also have enabled a limited supply of nurses to be used to the best advantage, as well as to reduce the incidence of hospital cross-infection. Unlike the United States, where each financially independent hospital has its own central sterile supply service, the grouping of hospitals in Britain under regional hospital boards means that the arrangements for central sterile supply departments may differ from group to group. This booklet describes some of the experiments which have taken place and will be of great value to those responsible for planning hospital services as well as the doctors and nurses who work in them.

The South African Museum

THE annual report of the South African Museum for 1959–60 records the completion of plans for the extension of the main Museum (Pp. ii + 19 + 4 plates. Cape Town: South African Museum, 1961). It also refers to the low scale of museum salaries and the consequent difficulty in obtaining personnel capable of assembling educational exhibits and undertaking research. The Board is endeavouring to establish equality of museum and university scales of pay. Several field trips were undertaken by the staff, most of them with the definite policy of collecting material to fill gaps in the collections. Remarkable progress has been made in the re-organization of several of the exhibition galleries, especially in the "Hall of Man", where the European Stone Ages are well illustrated, and a striking exhibit clearly shows the importance of South African ape men. An innovation in South African museums was the installation of earphones, by which visitors may, on inserting a coin, hear the calls of some common birds and at the same time see the animals in the case.

Modern Methods of Traffic Control

AN exhibition of modern traffic control arranged by the Westinghouse Brake and Signal Co., Ltd., will be on view at the Science Museum, South Kensington, during September 12–October 1, to coincide with the opening there, by Lord Brabazon of Tara, of the London conference of the International Commission for Transport Museums. It illustrates, by means of actual equipment and working models, a few of the types of device employed in controlling safely the more rapid flow of traffic on road and on rail. Particular attention is paid to those regions of British Railways undergoing electrification. The exhibition includes the 'Westronic' demonstration model, which shows how all the points and signals in a particular signalling location are controlled, some distance away, from a central control cabin, which also receives an indication of the condition of the remote points and signals and the position of trains passing through. There is also an automatic barrier machine and its associated equipment, which ensures that road traffic is stopped for the shortest possible time at level crossings. Other railway signalling equipment devised to prevent false operation or damage to it by interference from the traction system will be shown in model form. Among the road equipment is a road traffic-lane divider, for varying the width of traffic lanes at the approach to main junctions or cities according to the direction and volume of traffic.

British Regional Development Plan for Courses for the Diploma in Technology

A REGIONAL development plan for courses leading to the diploma in technology and the diploma in technology (engineering) has been drawn up by the Regional Advisory Council for Technological Education, London and the Home Counties, after consultation with industry, the Ministry of Education and the local education authorities in the area (*Regional Development Plan for Courses for the Diploma in Technology*. Pp. 16. London: Regional Advisory Council for Technological Education: London and Home Counties, 1961). It is the policy of the Council to encourage and build up such courses so as to secure maximum efficiency. The need for providing such courses in anticipation of the 1964 and 1965 period, when a major influx of eighteen- and nineteen-year-olds is expected, is kept in mind, as well as the requirements of industry. The development of 'end-on' as well as 'parallel' courses will be encouraged as one means of making the best possible use of available industrial training places, even though this may present problems of staffing and time-tabling in the technical colleges. Another method may be that of the 'thick' sandwich courses of at least three years full-time academic study, together with a minimum of one year of industrial training during the course, and the need for the continuing development of Higher National

Diploma courses will not be overlooked. Stress is laid on the need for flexibility in this development, of which a synopsis is included in the pamphlet, together with some notes on the particular courses.

The Harkness Fellowships of the Commonwealth Fund—New York

THIRTY Harkness fellowships of the Commonwealth Fund—New York are tenable during 1962 for education and travel in the continental United States. The fellowships are offered to candidates from the United Kingdom, Australia, New Zealand and Western Europe, who are British subjects and either are graduates or have experience in Government service, the professions, the arts, branches of business or industry or other comparable careers or vocations, and have the equivalent of a degree in qualifications conferred by professional bodies or an attested level of professional competence. Forms of application, which must be returned before November 15, can be obtained from the Warden, Harkness House, 38 Upper Brook Street, London, W.1, from whom further details can be obtained.

The Institute of Scientific Information

A BROCHURE describing the services, publications and techniques adopted by the Institute for Scientific Information (Philadelphia, Penn.) has now been issued by the Institute, to which Eugene Garfield, its director, contributes a foreword. He states that the primary purpose of the Institute is to increase the productivity of research through a programme of dissemination and retrieval of information, screening, coding and indexing systems, design, research and development. The brochure describes the scope of *Current Contents* and the *Index Chemicus*, the *Index Medicus* programme, the *Citation Index* project and the three projects still in development: the transliterating typewriter, the *National Newspaper of Science*, and the *National Directory of Science*.

Polish Textile Research

THE journal of the Politechnika Łodźka (*Zeszyty Naukowe Politechniki Lodzkiej*) is published in five sections, corresponding to chemistry, applied chemistry, electricity, mechanics, and textiles. Volumes 6 and 7 of the textile section have been issued, and provide some ten extensive papers on subjects ranging from the variable delivery of metering pumps to the cleaning of bast fibres by passing them through fluted rollers. The work is described in great detail (in Polish) with summaries in Polish, English and Russian. The reports are of high standard, and should be available in textile laboratories. Copies can be obtained from the Politechnika Łodźka, ul. Gdańska 155, Łodź.

Announcements

DR. FABIAN RECALDE, former director of the National Institute of Nutrition in Quito, Ecuador, has been appointed to the staff of the Food and Agriculture Organization as a nutrition officer. Dr. Recalde's task will be the co-ordination of field projects in Latin America that require joint action by the Organization and the United Nations Children's Fund. These projects chiefly concern improving material and child nutrition.

DR. E. L. POWERS, associate director, Division of Biological and Medical Research, Argonne National Laboratory, Illinois, will deliver the seventh Douglas Lea Memorial Lecture, entitled "New Considerations on Survival Curves and Target Theory", at a meeting of the Hospital Physicists' Association, at 5.15 p.m. on September 15, in the Chemistry Department, University of Leeds. Further information can be obtained from Dr. J. R. Mallard, Department of Physics, Hammersmith Hospital, Ducane Road, London, W.12.

THE fifth international conference on "Pigment Cell Biology" is being sponsored by the New York Academy of Sciences and will be held in New York City during October 11–14. The conference will deal with melanoma and closely related fields. Further information can be obtained from Vernon Riley, Sloan-Kettering Institute for Cancer Research, New York 21, N.Y.

THE fourteenth international instructional course on "Fine Measuring Instruments" is being held by Carl Zeiss, Jena, at the Imperial College of Science and Technology, London, during September 11–22. Further information can be obtained from Carl Zeiss Scientific Instruments, Ltd., 12*a* Golden Square, London, W.1.

THE newly formed American Society for Cell Biology is holding a meeting at the Edgewater Beach Hotel, Chicago, Illinois, during November 2–4. Three symposia are included in the programme, which will cover: cell continuity; cell diversification; characteristics of cell interfaces. Further information can be obtained from Montrose J. Moses, Acting Secretary, American Society for Cell Biology, Box 2982, Duke University School of Medicine, Durham, North Carolina.

THE Food and Agriculture Organization is sponsoring an international conference on "Fish in Nutrition" in Washington, D.C., during September 19–27. The programme will include: the role of fish in world nutrition; chemical composition of fish and fishery products; contribution of fish and fish products to national diets; fish and fishery products in animal nutrition; demand for fish as human food and possibilities for increased consumption. Further information can be obtained from the headquarters of the Food and Agriculture Organization, Viale delle Terme di Caracalla, Rome.

A COURSE for young naturalists with a strong interest in conservation is run annually by the Verein Naturpark in the Lüneburger Heide, North Germany. The participants are given first-hand knowledge of the theoretical and practical sides of conservation. Information can be obtained from the camp secretary of the International Youth Federation for the Study and Conservation of Nature, Reiner Lidauer, Paracelsusstrasse, 6, Salzburg, Austria, or from Derek S. Davis, 56 Altmore Avenue, East Ham, London, E.6, of the British Co-ordinating Group of the International Youth Federation.

ERRATUM. In the article entitled "Effect of Polyvinyl Alcohol on the Distribution of Iodine-131 in the Internal Organs, Fluids and Excreta of Rabbits", by H. F. Nowak and J. Kucharski, in *Nature* of August 12, p. 665, the sentence beginning at line 14 from the end should read: "Administration of iodine-131 with polyvinyl alcohol caused it to collect in smaller quantities in the parenchymal organs and thus the possibility of injury to these organs is considerably reduced".

INORGANIC POLYMERS

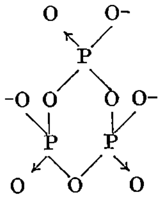
THE international symposium on "Inorganic Polymers", held at the University of Nottingham during July 18–21, attracted more than four hundred people, drawn from eighteen different countries. This response reflected the widespread interest in a subject virtually unmentioned a few years ago.

Contributions to the symposium were of two kinds: nine invited speakers gave full-length lectures, the texts of which are to be published by the Chemical Society; thirty-one shorter communications were presented and very briefly discussed. The most effective discussions were those which were held informally between sessions: these were facilitated by the fact that nearly all those attending were accommodated on the University campus. These social arrangements were excellent, and contributed in no small measure to the undoubted success of the meeting.

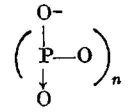
After the president of the Chemical Society (Sir Alexander Todd) had welcomed visitors in English, French, German and Russian, an introductory address was delivered by Dr. J. S. Anderson (National Chemical Laboratory). A main theme of this address was the problem, very fundamental to the symposium: "What is an Inorganic Polymer?" The theme recurred from time to time, and led to good-humoured exchanges suggesting rivalry between organic and inorganic chemists over polymers which might be described as organo-metallic, metallo-organic, or inorganic. Anderson pointed out that there are really two parts to this problem: (*a*) How large must the molecule be to be described as a polymer? (*b*) What restrictions of chemical composition are implied by the adjective 'inorganic'? On the first point, cyclic structures such as $(PNCl_2)_3$ occupied a prominent place in the discussions but are neither more nor less polymeric than, say, benzene. The second point is best dealt with by listing some of the types of polymer which were discussed during the meeting. They fall naturally into three classes: (1) polymers containing no carbon, for example, the chain forms of sulphur and selenium, $(PNCl_2)_n$, polyphosphates; (2) chain polymers in which the main chain does not involve carbon, for example, the siloxanes $(SiR_2—O—)_n$, where R is organic; (3) chain polymers in which carbon forms only a part of the main chain, for example, co-ordination polymers of the type $(—M—R—)_n$, where M is a metal and R an organic unit. The best compromise definition might insist on the absence of carbon from the main chain, and then include (2) but not (3). In point of fact, the wide range of materials surveyed by different speakers reflects the origin of much of the recent work in this field in a search for polymers capable of practical use at high temperatures. Since the object is to improve on the performance of organic polymers, large organic groups have been automatically excluded from consideration.

Before reporting on papers which dealt with specific polymers, one other general lecture may be mentioned. Prof. G. Gee (Manchester) directed attention to the large number of the systems under discussion which could exist in either chain or cyclic forms, the latter containing usually 6 or 8 atoms in the ring. He outlined a thermodynamic analysis of the equilibrium between ring and chain forms, pointing out that both heat and entropy of conversion ring/chain were likely to be small. In consequence, the equilibrium is readily displaced in either direction by small influences, and four classes of behaviour are possible: (i) chains unstable at any temperature; (ii), (iii) chains unstable below a 'floor temperature' or above a 'ceiling temperature'; (iv) an equilibrium chain concentration on any temperature. This analysis cannot yet be widely applied, due to lack of thermochemical data. In most of the systems described, equilibrium is not readily attained, and the product found in given circumstances is determined by kinetic factors.

One of the classical problems of inorganic chemistry is that of the structure of the many phosphates which have been described. A review of recent work in this field, given by Prof. E. Thilo (Berlin), showed that much confusion had been resolved by recognizing the existence of ring and chain forms, for example:

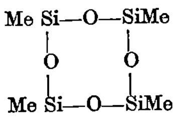


and



where n could reach values as high as 10^6. The chain forms may be either amorphous and soluble in water or crystalline and insoluble. The nature of the cation is of importance, in controlling the configuration of the chain and the crystal structure. The arsenates form a similar family, and mixed compounds, both cyclic and chain, can also be made.

Among the very few synthetic inorganic polymers which have already achieved industrial success the siloxanes occupy a prominent place. There have also been many attempts to modify the siloxanes by partial or complete replacement of silicon by other atoms. The lecture given by Prof. K. A. Andrianov (Moscow), who has been outstanding in this work, summarized some of his methods and results. Cyclic siloxanes such as $(SiMe_2O)_4$ are very well known, and Andrianov has described three-dimensional closed structures, including one which may be written as a cube having as its side:



Cyclic structures are readily opened by strong bases to give linear chains with terminal $—O^-$. Reaction of such a chain with an alkoxide of aluminium, titanium or boron is reported to lead to polycondensation, for example:

$$HO—(SiR_2O)_nH + Al(OR'')_3 \rightarrow HO—[(SiR_2O)_n—Al(OR')O]_x R$$

Vulcanizable elastomers having good physical properties have been reported.

A contributed paper by D. L. Alletson, A. G. Davies and B. N. Figgis (University College, London) described work on the dialkyl tin oxides, indicating the existence of tin analogues of both the ring and chain siloxanes. Four-membered rings are believed to occur among the stannoxanes.

Another well-known group of inorganic polymers are the phosphonitrilic compounds, of which the most familiar is the chloride $(PNCl_2)_n$, sometimes referred to as 'inorganic rubber'. In his lecture, Dr. C. P. Haber (U.S. Naval Ordnance Laboratory, California) summarized recent work, including several new general methods of synthesis. The usual procedure for the chloride involves reaction of ammonium chloride with phosphorus pentachloride (PCl_5), and can be modified to give $(PNR_2)_n$ by replacing PCl_5 by PCl_3R_2. This method always gives cyclic products; in the case of the chloride these are readily polymerized by heating. The chain polymer $(PNR_2)_n$ (R=Me, Et, Ph) cannot, however, be obtained in this way, as the ring does not open on heating. Reaction of $PClR_2$ with sodium azide leads, via R_2PN_3, to chain polymer. Substitution reactions can also be used to replace chlorine by other groups. By these various techniques, a considerable range of both cyclic and polymeric phosphonitrilic compounds have now been made.

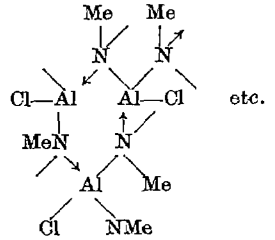
One of the most interesting problems associated with the phosphonitrilic compounds concerns their electronic constitution, that is, the nature of the P—N bond. In a contributed paper, N. L. Paddock (Manchester) reviewed this problem in the light of recent thermochemical and spectroscopic measurements and studies of base strength. There is no doubt that delocalized bonds are formed, both in rings and in the chain, by overlap of p orbitals of N with d orbitals of P. It is possible, on this basis, to understand why the stability of a PN ring is very much less dependent on its size than is that of a hydrocarbon $(CH)_n$. This problem was also referred to by Prof. A. B. Burg (Southern California) in his lecture. Discussing the polymerizability of the 6-membered ring $(PX_2N)_3$, Burg sought for factors tending to increase the size of the angle PNP, and on this basis deduced as the order of increasing polymerizability: $X = NR_2 <$ Me or Ph $<$ Cl $<$ F or CF_3.

Turning to BN polymers, Burg reported that the chain polymer $(Me_2N.BH_2)_n$ is unstable at room temperature, but the 6-membered ring ($n = 3$) is unchanged by heating at 300° C. The structure of this compound has been determined (by Lipscomb) and found to be of cyclohexane chair form, with ring angles of 113–114°. The corresponding phosphinoborine $(M_2PBH_2)_3$ is similar, with ring angles 118° (P) and 112° (B).

BN polymers were further discussed in the lecture by Prof. A. W. Laubengayer (Cornell) who represented three stages arising by progressive removal of RX from a co-ordination compound I of R_3N and BX_3:

$$\underset{\text{I}}{R_3N \to BX_3} \to \underset{\text{II}}{(R_2N \to BX_2)_n} \to \underset{\text{III}}{(RN—BX)_n} \to \underset{\text{IV}}{(BN)_n}$$

In series II, both B and N are approximately tetrahedral, but there is charge alternation in the ring or chain. Series III has as its parent member borazole $(NH—BH)_3$, which possesses a plane aromatic ring and closely resembles benzene. The corresponding chain is unknown: on pyrolysis borazole gives a variety of products, among which have been identified analogues of naphthalene and diphenyl. Boron nitride (IV) forms a layer structure very similar to graphite, but with B^- and N^+ alternating in adjacent layers. Aluminium–nitrogen polymers have been less studied, and there is no evidence for a borazole analogue. $(Me\ N.\ AlCl)_n$ is a very stable, insoluble material, possibly:

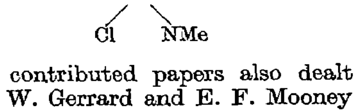


Several contributed papers also dealt with BN polymers. W. Gerrard and E. F. Mooney (Northern Polytechnic, London) reported that borazole ring formation could be prevented by bulky substituents (III, R = P or Bu, X = Ph). J. Dewing (Imperial Chemical Industries, Billingham) reported the polymerization of $Me_2N.BH_2$ by heating at 150° C. and 3,000 atm., to an amorphous, infusible, insoluble polymer, which slowly reverted to a cyclic dimer under ambient conditions.

The two remaining lectures, by Prof. J. C. Bailar (Illinois) and Prof. O. Schmitz-Dumont (Bonn), both dealt with co-ordination polymers. The underlying principles are straightforward, though their application to produce useful polymers has not yet been successful. The most useful technique involves polymerization by co-ordination, and requires the use of a bi- or poly-functional ligand. A very simple example is

$$Ag^+ + NH_2(CH_2)NH_2 \to \\ \to Ag^+ \leftarrow NH_2(CH_2)_2NH_2 \to Ag^+ \leftarrow$$

A metal of higher co-ordination number can form chelate rings; use of *bis*-diketones then leads to very stable polymers such as



where X is any linking unit such as $(CH_2)_n$ or C_6H_4. A variation on this procedure involves linking together, for example, by polycondensation, units which are already co-ordinated, that is, making the X bridges. It will be seen that the 'inorganic' content of such a structure is extremely small.

In this review of the symposium, no attempt has been made to mention all the contributors or all the topics discussed. It will be clear that the emphasis was on the preparation of polymers. The symposium offered a timely opportunity to take stock of the present position, and should lead to some reorientation of future effort. While there is clearly much synthetic work still to be done, increasing attention should now be given to reaction mechanisms and energetics, and to the physical study of the products. Prof. C. C. Addison and his colleagues on the organizing committee are to be congratulated on a most successful venture, which may well exercise an appreciable influence on the development of the subject.

G. GEE

SOCIETY OF EUROPEAN NEMATOLOGISTS

AT the invitation and under the presidency of Prof. J. van den Brande, the sixth international nematology symposium of the Society of European Nematologists was held during July 24–28, 1961, at the State Agricultural College in the ancient and beautiful city of Ghent. From some twenty-seven countries came about 140 participants, the largest contingents being those from Belgium (thirty-three), Great Britain (thirty, after deducting four for overseas students), Germany, West and East (nineteen), and Netherlands (seventeen).

After the inaugural presidential address and a stimulating special lecture by Prof. de Coninck on "Problems of Systematics and Taxonomy in Nematology today," there followed some fifty papers, grouped after the first day under two simultaneous sections, and each ostensibly limited to 20 min., including time for discussion.

Lack of space precludes a reference to every paper, but some of the trends and highlights can be briefly indicated.

In the field of taxonomy a paper by B. G. Chitwood (presented in his absence by A. L. Taylor) described and illustrated photographically the holotype and allotype specimens of most of the recognized *Meloidogyne* species and sub-species. These specimens were selected in 1960 by a committee of the American Phytopathological Society. Chitwood regards these taxa as possibly polyphyletic, originating as repetitive mutants ; at least one (*M. javanica javanica*) is probably a defective triploid.

W. C. Clark commented on the variability and accuracy of linear measurements used in systematics, and of ratios based on them. The de Man ratios, based on total length, are of little value when the latter is highly variable; also, they presuppose absence of allometric growth. H. Gysels showed that in *Panagrellus silusiae* post-embryonic growth is in fact allometric with respect to length: moreover, in the expression $y=Kx^a$, the index may change at different stages in the life cycle.

Among matters of life-history and biology, A. M. Shepherd showed that *Heterodera göttingiana* larvæ emerged from cysts in soil, in the presence of a host, even more readily than *H. rostochiensis*, but could not be made to emerge *in vitro*. In tissue-culture experiments with *Meloidogyne*, M. L. Schuster and R. M. Sandstedt found that movements of larvæ were consistent with a random walk and accidental contact with roots rather than with an attraction mechanism. W. H. Lavallee and R. A. Rhode, on the other hand, interpreted the rapid concentration of *Pratylenchus penetrans* around a host at one end of a box as due to attraction.

The orientation of *Ditylenchus dipsaci* to physical stimuli was discussed by H. R. Wallace : in gradients of temperature, moisture, and size of sand particles, the worms preferred 10° C., high moisture, and fine sand.

The feeding mechanisms of Rhabditids and Tylenchids were interestingly compared in a film by C. C. Doncaster. The movements of dye globules and air bubbles through the œsophagus were analysed, the bubbles showing change in size with pressure. He also showed a film on nematode predators.

The geographical or topographical distribution of nematode populations was discussed in several papers. M. Ritter was able to correlate the distribution of species of *Meloidogyne* in France with climatic zones. J. de Maeseneer reported on the distribution of some of the chief migratory root nematodes in Belgium. E. Gadea gave data on the free-living nematodes of freshwater and moss biotopes in Spain. B. Weischer has made the ecologically interesting discovery of two species of Desmoscolecidae in vineyard soils from a small area centred on Bad Ems: the point is that most other species of this family are marine. A. B. Oteifa usefully summarized the chief plant nematodes of crops in Egypt.

Changes in nematode populations were dealt with by S. Stemerding, who counted *Tylenchorhynchus dubius* and *Rotylenchus robustus* in weekly samples from a monoculture of peas. R. Gair *et al.* found differences between varieties of spring barley in their effect on rate of increase of *Heterodera avenae*. M. Oostenbrink presented the results of examining numerous samples from meadows and arable land in the Netherlands. It is clear that the heaviest populations of nematodes come from the grass/clover crop from meadows. Many of these nematodes are plant parasites and are important in two ways: some are harmful to the grass/clover crop itself, and some become harmful on arable crops when the meadow is ploughed. K. Kuiper is tracing the gradual invasion of new polder-soils from the Zuider Zee area by plant nematodes, and the factors responsible for this invasion.

In the field of pathology, H. Goffart has shown that one effect of *Ditylenchus dipsaci* in sugar beet is to increase the content of reducing sugars; this also occurs with *D. destructor* in nutrient-agar cultures and to a smaller degree with *Heterodera rostochiensis*. The effect is ascribed to enzyme action from the œsophageal glands.

The importance of nematodes as vectors of virus pathogens was stressed by R. S. Pitcher. All the known cases belong to the Dorylaimoidea and are of two types: some 'ring-spot' viruses carried by nematodes of the Longidorinae, and tobacco rattle virus carried by *Trichodorus*. H. H. Sol showed that *T. pachydermis* appears to be the only transmitter, nematodes extracted from infected soil retaining the virus for at least three weeks.

An interaction between *Verticillium albo-atrum* and *Pratylenchus penetrans* has been shown by W. B. Mountain and C. D. McKeen, the nematode being more prevalent in the presence of the fungus.

L. Roguska-Wasilewska found that *Heterodera schachtii* inhibited the respiration of rape far more than did the saprophagous *Eucephalobus elongatus*.

Other disease situations included: *Ditylenchus dipsaci* increasingly causing collar-rot of beet in Switzerland (A. Savary); *D. radicicola* of Dutch strain damaging *Poa annua* but not barley, whereas the Swedish strain behaves in the reverse manner (J. J. s'Jacob); *Radopholus similis* causing root-rot in banana in New South Wales (C. D. Blake).

Numerous papers dealt with control methods. Outstanding were a tabulated compilation of reported crop-yield increases as a result of using nematicides in the United States, comprising 853 comparisons (A. L. Taylor), and a succinct account of the way in which *Heterodera rostochiensis* is held in check on Long Island by nematicidal treatment (chiefly with dichloropropene), cultural methods and legal regulation, and the use of resistant varieties of potato in fields where the nematode population remains below the level of discovery (W. F. Mai and M. B. Harrison).

The diffusion of ethylene dibromide through soil was shown by F. Call and N. G. M. Hague to be largely determined by soil porosity; relating chemical to bioassay determinations, they found that very low concentrations persist for long periods. H. W. Nolte found only temporary benefit from using 'Vapam' against *Pratylenchus* in pine nurseries, and K. Raschke showed that reduction of hatching from *Heterodera* cysts after treatment with 'Trapex' was due not to delayed hatching but to death of larvæ.

Ultrasonic vibrations, tested by L. Kaempfe, gave disappointing results, especially against encysted *Heterodera* larvæ.

Radiotracer techniques using phosphorus-32 were applied by B. A. Oteifa and D. M. Elgindi to a study of galling in tomatoes by *Meloidogyne javanica* and its effect on uptake of nutrient, and by F. Sprau and A. Suesz to indicate that *Longidorus maximus* feeds on the roots of beet and is thus a parasite; and, using carbon-14, were adapted by B. M. Zuckerman to estimate the amount of plant fluid ingested by a single nematode.

At the biennial general meeting on July 27 members of the Society heard an encouraging report from the secretary, Dr. Lindhardt, who was able to show a steady growth in membership over the years:

1957: 141 members from 19 countries; 1959: 179 from 25 countries; 1961: 218 from 33 countries (of this last total, 166 come from Europe).

An invitation from Dr. John Grainger to hold the seventh symposium at Auchincruive in September 1963 was accepted with enthusiasm, and Prof. Nolte tabled an advance invitation to Aschersleben for 1965. It was decided to issue to members a duplicated 'Newsletter' under the editorship of Dr. Lindhardt, assisted by a corps of reporters.

A lavish social programme included a civic reception at the Town Hall, a dinner at the Castle of Laarne, and a lunch at the Park Hotel, Lokeren. There was also a programme of daily excursions for non-participating ladies.

Translator-in-chief, displaying equal facility in the three official languages besides his native Flemish, was Mr. R. Kips (secretary).

B. G. PETERS

A NEW LABORATORY FOR RESEARCH ON CREEP

ON July 6 the new Creep Laboratory of the British Electrical and Allied Industries Research Association was opened at Leatherhead by Dr. Charles Sykes, managing director of Thomas Firth and John Brown, Ltd. Its purpose is to carry out an extended programme of long-term co-operative research and investigation on the creep of steels in conditions of high temperature and mechanical stress.

Increase in the overall efficiency of generation of electrical power by steam now turns critically on improving the thermodynamic efficiency by operating at higher temperatures and pressures. The limiting factors in practice are set by materials capable of withstanding these conditions during long periods. The highest temperatures (above 600° C.) are found in superheater tubes, steampipes and control valves, but conditions are even more onerous in turbine rotors, blades and casings where tolerance to distortion is very small.

Historically, progress in steel development has occurred in three phases. Initially, power-station plant was constructed entirely of plain carbon steel; this was followed by the addition of small amounts of alloying elements which added strength to the steel. Now, in the third phase, special highly alloyed stainless steels are being developed. The cost of such steels is high and is reflected in the great increase in the proportion of cost of steam-raising equipment in modern power stations. Such increases must, in the long run, be offset by increased efficiency, and this can only be judged when full knowledge of the life and reliability of these new steels is available. Creep, which can be defined as permanent deformation of materials arising from continued stress, is of basic importance in this connexion.

The investigation of the properties of high-temperature steels for power stations was inaugurated as long ago as 1930 by the Steels for High Temperature Committee of the Electrical Research Association. Most of the investigations until recently have been carried out by the Metallurgical Division of the National Physical Laboratory and at the National Engineering Laboratory. In 1957 work was started at the Electrical Research Association to supplement that at the National Physical Laboratory. The National Physical Laboratory is, however, no longer able to cope with the vastly expanded programme, and through the joint efforts of the Committee it has been possible to centre all the work in the new buildings and equipment installed at Leatherhead.

The main Laboratory is 140 ft. long and 45 ft. wide. It has space for about 250 units for testing creep. Since these units dissipate considerable heat it has been necessary to install air-circulating equipment to maintain a suitable ambient temperature for instrumentation and personnel. The bulk of the units are designed to record either the creep or the time of rupture of standard samples cut and very accurately machined from bars of steel or from fabricated parts. At present there are fifty units of high sensitivity fitted with Martens optical extensometers. These machines are designed particularly for studying the creep behaviour of turbine rotor forgings, blades and casings, and are at present also being used for the creep of metal weld deposits and the parent metal. There are fifty large rupture machines, in which ten specimens can be stressed simultaneously end to end. They do not record the creep but only the time to rupture. They are used to provide long-time design data for high-alloy steel steampipes and superheater tubes. The stress applied to the specimens is varied so as to produce rupture times extending from about 300 to 10^5 hr. Graphs of rupturing time against stress are then used to predict the life under the stress conditions found in service. The variation from cast to cast within a particular specification is under investigation.

There are a further fifty dual-purpose creep/rupture units which can be used either as specimen rupture machines or as creep machines using dial gauge extensometers where less-accurate creep measurement is required. They are at present employed in measurements on turbine casings. One large machine with 15-ton loading has been installed for rupture-testing of full sections of steampipe.

The temperatures of the specimens are maintained by electric furnaces, the range of temperature of which at present extends from 450° C. to 700° C., but can be raised above this temperature when future requirements demand. The furnace temperature is maintained automatically by an electronic controller, to within ± 3° C. up to 600° C. and to within ± 4° C. above 600° C. Temperatures of the specimens themselves are measured by means of thermocouples (of which there are three on each specimen) in the high-sensitivity units. The thermocouple readings can be channelled selectively to a central control desk for manual measurement, but during critical periods they can be connected to one of 36 continuous recording charts situated in the Laboratory. In the rupture units there are five thermocouples distributed among the ten specimens. These, too, can be channelled to the control desk.

Another important project which is being undertaken in the new Laboratory is the testing to destruction of thick-walled tubes by applying steam pressure for long periods of time at temperatures encountered in service. This enables the creep data obtained in the Laboratory to be correlated with data on actual tubes so that the expected life in practice can be assessed. In testing creep in the Laboratory only a single uni-axial stress is applied whereas a steampipe is subjected to a complex stress system. Four such test rigs have been operating in the Electrical Research Association during the past three years. There are now fifteen rigs.

The data obtained in the new Laboratory will be subject to constant scrutiny as a means of providing more understanding of the mechanism of creep resistance of high-temperature steels. Knowledge of this kind will almost certainly be of benefit in the future development of steels for still higher temperatures, the demand for which is likely to continue for a long time.

CLIMATOLOGY AND CONSERVATION IN MUSEUMS

THE Commission for Museum Laboratories of the International Council of Museums and the International Study Centre for the Preservation and Restoration of Cultural Property have recently undertaken a world-wide inquiry into the subject of environment in relation to conservation. Replies from sixty-four institutions to a questionnaire on the subject, and further study of the situation thus revealed, form the basis of a 46-page report*. In it, museum curators, rather than scientists specializing in conservation, are provided with a useful compendium on the atmosphere and its contaminants, hygrometry, instrumentation and equipment for the control of museum climate. In addition there are several useful reference tables relating to conditions within and outside museums in various parts of the world.

As is proper for documents issued by an international organization, several authors from various European countries have contributed, but the actual publication consists of complete texts in French and in English. Taking into account the polyglot sources of the material, the effort can only be said to have been altogether praiseworthy. Moreover, the fact that the report is written for curators who must be assumed to have little knowledge of the physics involved, must have added to the task. Faced with this requirement, however, it is unfortunately all too easy to stray away from rigorous scientific exposition for the sake of a tempting analogy. For example, it may be acceptable in the introductory paragraph to compare inanimate objects with human beings in their reaction to the environment: "They live and breathe in the sense that there is continual if imperceptible change arising from their *adaptation* to the ambient conditions of the museum"; but, is it wise to persist with: "Some objects have a surprising capacity for *adapting* themselves to environment apparently without deleterious effect. Thus, a particular piece of wood or bronze may be recovered in remarkable condition after having been conserved for centuries in a swamp or bog; or a certain picture which has been exposed in a damp church may survive the ill-effects beyond all expectation. Let them be brought from their accustomed *habitat* into a museum, however, and the true state of affairs will soon be manifest, even where the atmosphere is rigorously conditioned" ? (p. 243). Again: "The crux of the matter is to be found in the past history of the specimen, its structure and the conditions to which it has already become *acclimatised*. As is well known, even the best museum conditions can be dangerous for a painted panel that has been normally housed in a cold, damp country house" (p. 253). This may or may not be a phenomenon which is observable under scientific control, but if it is, to imply a conditioning process in the biological sense only helps to perpetuate the notion which is sometimes present among curators that objects, particularly paintings, lose their 'resistance' in the soft environment of the air-conditioned gallery and decay, or alternatively, become unfit to withstand uncontrolled conditions.

Where the equilibrium that the object will attain in the museum results in a considerable change in moisture content, there will obviously be undesirable —often catastrophic—volume changes. Special techniques have been developed for dealing with such cases as, for example, water-logged wood. But it is difficult at first to entertain the idea that stabilizing the atmosphere at parameters well within those of the natural cycles can be harmful. Evidence on the alleged phenomenon is unfortunately biased for the simple reason that objects are closely and regularly inspected once they have entered the museum—but not before. Even so it is not without interest to proceed on hypothetical lines because it is the experience of every curator that certain objects prove intractable. It might be supposed, for example, that continual swelling and shrinking prevents embrittlement in organic materials. Another possibility is connected, not unreasonably, with gradients in moisture content within the object. Certain forms of deterioration in paintings (both panel and canvas) can be shown undoubtedly to result from the gradient set up when the back is in close proximity to what may be a cool and/or damp wall, while the front enjoys constant and ideal but different conditions. It cannot be assumed that such steady-state conditions are *a priori* more favourable on all counts than cyclic ones in which even a reversal of the gradient is possible. The transfer of soluble material, whether salts or adhesives, within the object is a source of breakdown, particularly at an interface where the structure is laminar. The report does not deal with this phenomenon beyond pointing out that the variation in climate within a room may be such as to produce a 12 per cent variation in relative humidity over 3 m. in height. The importance of moisture content gradients relative to the main hazard—the swelling and shrinking of hydrophilic gels—is a matter for investigation. The result may well explain the unexpected results of air-conditioning which sometimes disappoint the curator. In so many investigations connected with conservation the actual number of variables is difficult to define, and generalizations are often misleading. A case in point is the assumption (p. 247) that picture canvases become slack when the atmosphere is over-dry, as raw natural fibre textiles do. The converse is more often observed because the textile behaviour is opposed by that of the animal glue with which it is impregnated—old masters made use of this effect to tension their canvases.

VIEWING AND LISTENING

A YEAR ago the British Broadcasting Corporation published a report of an audience research inquiry under the title *The Public and the Programmes*. The interest which this aroused has encouraged the Corporation to make available other findings of its Audience Research Department. *Facts and Figures about Viewing and Listening** offers, in a series of twelve charts, some facts which are important to a proper understanding of what has been happening to viewing and listening habits in recent years.

Each chart has its accompanying commentary explaining the significance of the matter dealt with and directing attention to outstanding points.

Charts I and II show the extent to which the British public uses the three broadcasting services, BBC Sound, BBC-TV and ITV. This is assessed in two ways—in terms of the numbers who typically listen (or view) in the course of a single day (that is, the numbers of 'patrons'), and in terms of the average number who are listening (or viewing) at any given moment (that is, the 'average audience').

Chart I, "The Patronage of Broadcasting", shows the number of adult 'patrons' for each service quarter by quarter for the past three years and shows that the number of adult patrons of BBC Sound has not fluctuated very greatly (this, despite the continuing increase in television coverage). The numbers of adult patrons of both BBC-TV and ITV have shown a rising tendency, with a seasonal fluctuation. The number of BBC-TV adult patrons is consistently above that of ITV because, if for no other reason, though all viewers can see BBC-TV, some cannot yet receive ITV.

The curves for child-patrons show that a much smaller proportion of children than adults patronize Sound and a larger proportion of children patronize ITV than patronize BBC-TV.

In Chart II a different picture emerges when the services are compared in terms of 'average audience' than when they are compared in terms of 'patrons'. Thus, Sound's patrons exceed those of either television service, but its average audience is much smaller than that of BBC-TV or ITV. The explanation lies in the fact that the average patron of sound listens for a relatively small proportion of the time during which sound broadcasting is transmitted. Similarly, though there are more patrons of BBC-TV than of ITV, the former spend less time viewing (1 hr. 44 min. a day) than do the latter (2 hr. 12 min.); hence the number who are viewing ITV at any given moment (7,500,000) is greater than the number who are viewing BBC-TV (6,350,000).

Chart III shows the relationship, since 1952–53, between the amount of time (in the evening) during which television programmes were broadcast and the amount of time which the average viewer actually spent in viewing. Two points emerge from this comparison: (1) that an increase in the number of television programme hours in the evening is not followed by a proportionate increase in viewing; (2) that, since commercial television became available, there has been little difference between the amount of time spent in evening viewing by those who could receive both BBC and ITV and by those who could only receive BBC-TV.

These results suggest that the introduction of further television services (a third and perhaps a fourth) will be unlikely to cause an increase in the total amount of time which people devote to viewing.

Charts IV and V illustrate the way in which people with multichannel receivers distribute their viewing between BBC-TV and commercial television. Chart IV shows the proportions which, on the average day in each quarter of the past two years, confined their viewing to BBC-TV, viewed both BBC and ITV, confined the viewing to ITV, or did not view at all. The last of these categories tends to vary seasonally, being greatest in the July–September quarter. Apart from this, there has been a tendency in the past two years for fewer adults to confine their viewing to ITV and for considerably more to view both services. Among children, many more restrict their viewing to ITV than restrict it to BBC-TV.

---

* British Broadcasting Corporation. *Facts and Figures about Viewing and Listening*. In Twelve Charts with a Commentary. Pp. 31. (London: British Broadcasting Corporation.) 5s. net.

Chart V shows how Band 1/3 viewers have divided their evening viewing time between BBC and commercial television. The trends are remarkably similar: when commercial television first comes to a region there is usually a period of 'settling down' during which the proportion of time given to BBC-TV tends to fall. Then relative stability is reached.

Chart VI relates to the way evening viewing is divided between BBC and ITV according to the educational level of the viewer. Among those whose full-time education continued up to and beyond the age of seventeen years, roughly half view BBC-TV either virtually exclusively or more than they view Independent Television. Those in this group who view ITV exclusively or predominantly are a minority, 37 per cent. In the group whose full-time education was not continued beyond the age of fifteen or sixteen, about 30 per cent either always view BBC or view it more than ITV, whereas 52 per cent, always or more often, view ITV. In the group whose full-time education ceased at fourteen years or earlier the corresponding proportions are 20 per cent and 65 per cent respectively.

Chart VII shows the present comparative quantities of listening to sound broadcasting at different times of the day. The period when there is most listening is shown to be that between noon and 2 p.m. when the average audience is nearly 5·5 million. The main point brought out by the chart is that 'levels' of listening in the afternoon and evening are now far lower than those in the morning; in the evening sound broadcasting must compete with television.

The 1950–60 trends in the day-time and evening audiences for sound are shown in Chart VIII. During the period 6–11 p.m. Sound's audiences declined sharply each year with the result that, for every four people who were listening in January–March 1950, only one was doing so ten years later. Between 9 a.m. and 6 p.m., on the other hand, when the competition of television was less fierce, audiences for sound showed no comparable decrease. For every four people listening in the winter of 1950, three were doing so ten years later.

Chart X shows how much time 'listeners' and 'viewers' have spent with sound broadcasting in the evening each autumn since 1954. The average adult 'listener', far from reducing his evening listening, has tended to increase it in the past six years. He now listens for about 1 hr. (out of a possible 5) a night. The average 'viewer', on the other hand, has never listened much in the evening. This small average quantity of listeners guarantees Sound broadcasting a considerable audience in the evening. Even if the time should come when virtually everyone has a television set, the audience for sound broadcasting in the evening would still, at this rate of 'viewer-listening', be about one million persons.

Chart XI shows the extent to which, during October–December 1960, children aged five to seven, eight to eleven, and twelve to fourteen years viewed television between 5 and 6 p.m. and in the first half of the evening, 6–9 p.m. Each day between the hours of 5 and 9 p.m. the average child of five to seven years and the average child of eight to eleven years, watched television for more than two hours, while the average twelve to fourteen-year-old watched for nearly an hour and a half—and in each case the bulk of this time was spent in viewing programmes after 6 p.m.

Between 5 and 6 p.m., the older the child the greater is the share of such time when he views which he devotes to BBC-TV. During the early evening, on the other hand, the reverse is true: the older the child the smaller is the share of his viewing time which he spends with BBC-TV.

Chart XII shows that the size of an audience is, by itself, no sure guide to its popularity. The Chart illustrates this by showing that, during four typical weeks in mid-winter 1960, there were fourteen BBC-TV broadcasts each of which had an audience numbering approximately six million persons yet varied widely in the extent to which they were enjoyed. At one extreme one broadcast had a reaction index (the BBC's yardstick of 'enjoyment') of seventy-nine (out of a possible one hundred), while at the other was one with a reaction index of forty-nine. Thus, had 'audience size' alone been accepted as the criterion of popularity, these two broadcasts would have ranked as equal, whereas it is clear that those who saw Broadcast No. 1 enjoyed it far more than those who saw Broadcast No. 14.

EDUCATION OF BACKWARD CHILDREN IN BRITAIN

SINCE the War there has been a three-fold increase in the number of places available in special schools in Britain for educationally sub-normal children, the figure having risen from 11,000 in 1946, to 34,500 at the beginning of this year.

Educationally sub-normal pupils are defined as "pupils who, by reason of limited ability or other conditions resulting in educational retardation, require some specialized form of education wholly or partly in substitution for the education normally given in ordinary schools". They form one of ten categories of handicapped pupils for whom special education is provided. There is no overall national deficiency of places for blind, partially sighted, deaf, partially deaf, epileptic, physically handicapped, delicate and speech-defective children, although for some of these handicaps local improvements can be and are being made.

In a circular to local education authorities (11/61) Sir David Eccles, Minister of Education, estimates that a further 19,500 places will be needed to cater fully for all the educationally sub-normal children requiring education in special schools.

The Minister has already announced building programmes for the years up to March 1963 to provide about 10,000 of the places and intends to approve programmes, as soon as practicable, to provide the remainder.

The circular discusses the role of parents, teachers and doctors in discovering backwardness among children and in assessing their needs and the various measures that may be taken to enable them to live useful and independent lives. There has been a substantial increase in the rate at which children are brought forward for assessment since the War, during which time the school population has risen from 5 million in 1946 to 7 million in 1961.

Backwardness may be due to limited ability or other causes such as illness, a break in schooling or a disturbed home background. Many of these children will not need the specialized treatment given in special schools and can be given suitable education in ordinary schools. On the other hand, boarding schools or boarding homes are required for a small minority whose special education needs to extend to their life outside the classroom, for children whose home environment is such that they are unlikely to make good progress unless removed from it, and for those who do not live within reach of a special day-school. Each child's needs should be carefully assessed and should be kept under regular review.

The provision of extra places in special schools and the increasing interest in the needs of backward children in ordinary schools will require a substantial increase in the number of teachers for the educationally sub-normal. Teachers who wish to specialize in this work can attend one-year courses in the education of handicapped children, which are mainly concerned with backward children. In 1962 there will be 16 of these courses taking 250 teachers in all; in addition, a number of shorter courses is available.

The adjustment from school to working life is more difficult for these children than for those of normal ability but can be made easier by the advice of the youth employment officers in finding suitable jobs and by sympathetic guidance and help whether in the form of further education or informal activities arranged by their former schools.

THE BUILDING RESEARCH STATION

THE open days, July 10–13, held by the Building Research Station, Garston, Watford, Hertfordshire, were primarily for the benefit of the building industry—architects, builders, surveyors and building materials manufacturers—leaving aside research in structural engineering, but much of the work displayed was, as might be expected, of general scientific interest. Indeed, the open days were coupled with the official opening by Sir Harry Melville, secretary of the Department of Scientific and Industrial Research, on July 7, of a new laboratory for physical and chemical research on building materials. The building has been erected by the Ministry of Works (superintending architect, Mr. H. A. Snow; superintending engineer, Mr. M. Woolfson; main contractor, Wilson, Lovatt and Sons, Ltd.) as part of the general building programme for the Station. It replaces more than a dozen war-time huts and brings together in one building all the laboratory research on building materials that the Station carries out. In opening the laboratory, Sir Harry Melville referred to the frequently expressed view that good research results most frequently come from unpromising surroundings and primitive apparatus. "Nothing", he said, "can be further from the truth in these days." He went on to point out that the scope of the work of the Station had broadened enormously since its foundation forty years ago, but that materials research is still basic to the whole of the building industry.

Although, as Sir Harry Melville said, materials research is the oldest part of building research, it has always been prosecuted with the best scientific tools of the day and with the most up-to-date techniques. Thus at present electron microscopy, X-ray analysis, infra-red absorption spectroscopy, differential thermal analysis, high-temperature microscopy and microwaves all find application. The Station has indeed been a pioneer in the use of high-temperature microscopy directed to investigations of silicate minerals, and has developed a rapid and elegant technique for observing under the microscope reactions taking place at temperatures up to 2,400° C. A similar technique applied in the development of an X-ray camera for use up to 1,850° C. was also on view.

Micro-waves find application in equipment (now available commercially) designed to investigate the dampness of walls, a technique that is being further developed into a promising method of destroying dry rot by the heating effect of the waves, and radioactive techniques in the measurement of the wear of floor-surfacing materials.

Much of the research into building materials is devoted to a study of their fundamental physical and chemical properties, with the dual aim of providing a background of knowledge against which the durability of materials can be judged and of guiding new developments. Among the examples demonstrated were phase-equilibrium investigations on multi-component aqueous systems designed to increase understanding of the slow chemical reactions that materials undergo in use, and of the distribution of pore-size which has a close bearing on their resistance to frost. Laboratory abrasion tests for flooring materials have been notoriously unreliable, but following an investigation of the forces applied by the foot to the floor a new type of testing device was demonstrated that reproduces these forces.

New forms of construction make new demands on materials and throw up their own problems. Many curtain walling systems rely for their satisfactory performance on mastic materials for jointing. Thermal movements may be comparatively large and may make heavy demands on the mastic. Here the work of the Station has been mainly directed towards the assessment of the properties needed and the development of tests that can be used to evaluate the performance of jointing and caulking materials. The tests demonstrated dealt with rates of movement, stiffening with time, adhesion and load-bearing.

One of the great strengths of the Station is its ability to tackle most—if not all—aspects of problems involved in the development of new materials or processes. This is illustrated by its work on the perforated brick, the manufacture of which was demonstrated during the open days in the pilot-scale laboratory equipped with standard brick-making machinery. Not only has the Station been able to study the development of the design of the brick from the point of view of manufacture and æsthetic acceptability, but also it has been able to study strength, thermal properties, laying methods, rain resistance, and costs.

Visitors were able to see demonstrated the work of the Station on the packaging of building materials and the various units of mechanical plant developed for their handling; methods for fixing and joining plasterboard linings for house interiors, developed so as to remove as much of the wet process from building as possible; and the production of lightweight aggregate from pulverized fuel ash.

Of much current interest is the work on heating, as, for example, of flats, employing an electrical analogue, and of heat transmission through walls and roofs.

Equally topical is the survey being carried out of noise in London. One of the recording vans was on view, as was the main mobile acoustics laboratory, admirably equipped for almost any acoustical measurement and largely used for the measurement of sound transmission in buildings and for investigations into the laws governing the propagation of sound through the atmosphere.

The use of models finds considerable application in studies of the lighting of buildings, for, when suitably designed, they provide a ready means of obtaining both a factual and a subjective judgment of proposed schemes. The Station is active in establishing the principles on which permanent artificial lighting can be used to supplement day-lighting and thus give a new freedom to architectural planning. Closely associated with lighting is the use of colour in buildings: the one can modify considerably the effectiveness of the other. The range of colours for paint established as *B.S.* 2660 is now widely accepted, and the Station is engaged in trying to get the principles underlying the paint colours applied to building components such as tiles, linoleum, and plastics.

Allied to the physical investigations were the more subjective studies on the needs of users, illustrated by work on the design of drawing offices and of dwellings for old people.

Another use of three-dimensional models is found in the design of engineering services, and an exhibit showed ways in which they can help to resolve problems in the design of hospitals.

The economic aspects of building design and construction formed another exhibit on a topic of much importance. Here were shown investigations on the influence of the design of flats on their cost, the assessment of the comparative costs of different forms of urban development, and the programming of the sequence of work on building sites.

Altogether, there was much for the main target of the open days—architects and builders—to ponder over. The value of the open days for scientists is perhaps best exemplified by the director of a research organization in an entirely different industry, who went away having seen three pieces of work of immediate application in his own field. Some 3,500 visitors attended.

A NEW 'WEDGE' TYPE INSTABILITY OBSERVED IN A 'THETA' PINCH

By J. K. WRIGHT, R. D. MEDFORD, J. D. HERBERT and R. C. POTTINGER

Atomic Weapons Research Establishment, Foulness, Southend-on-Sea

RECENT experiments by Niblett and Green[1] have shown that flutes are developed on the outer surface of a plasma produced by a theta pinch and these are interpreted as magnetohydrodynamic Rayleigh–Taylor instabilities produced by the acceleration of the interface separating the driving magnetic field and the plasma. Josephson has recently reported another experiment in which he investigated a possible mechanism for neutron production in a theta pinch with reversed trapped magnetic field[2]. Niblett has said (private communication) that in his experiments with Green they made detailed magnetic probe measurements and these showed that in their experiment parallel trapped field was obtained on the second half-cycle. In both experiments high-speed camera shots were taken of the end view of the plasma during the second half-cycle of the discharge.

We have been studying similar phenomena in theta pinches but have made our observations during the first half-cycle of the discharge. The theta piece used was 7·5 cm. long, 3·4 cm. internal diameter and this was wound around the middle of a quartz discharge tube 22 cm. long, 3·0 cm. diameter filled with deuterium gas at pressures of the order of 1 mm. of mercury. Our condenser bank had a capacity of 40 μF. and was charged to a voltage of 10 kV. An explosive type switch discharged the bank through the theta piece. The parameters of the experiment were such that we obtained[3] a cylindrically converging shock wave on the first half-cycle with trapped magnetic field parallel to the driving field.

Photographs of this discharge have shown an interesting new phenomenon; during the first half-cycle of the discharge we see bright radial 'wedges' with less luminous plasma filling their interstices. Even with radial wedges present it appears that there is still magnetic field trapped by the imploding plasma. About the time of maximum compression it forces its way out of the centre by pushing the plasma in the interstices out towards the wall of the discharge tube, thereby forming flutes which appear to have trapped magnetic field inside them. These outgoing flutes grow into a fascinating octopus pattern similar to that observed by other workers and associated with a rotation of the whole plasma. In our experiment the flutes grow in amplitude following a curved line giving an impression of rotation.

The number of wedges seems to be determined by the irregularities in the system since it can be varied by deliberately introducing irregularities in the external conductors. Figs. 1, 2 and 3 show high-speed framing camera records (about 8 frames per μsec.) of the theta pinch on the first half-cycle of the discharge. Figs. 1 and 2 are of theta pinches fired in the *Prize*[4] apparatus (Fig. 8), where it will be noticed that there are 16 wedges, that is, half the number of wires in the return conductor normally used for the *Z* pre-ionizer. Fig. 3 is taken with the return conductor removed and the theta piece wound directly on to the discharge tube, and shows that the wedges are randomly spaced and fewer in number; Fig. 3 is particularly interesting because it shows the trapped magnetic field apparently pushing its way out of the plasma through the three gaps where the plasma luminosity is least. The resulting outgoing flutes are also seen to grow as a result of the pressure exerted by the trapped magnetic field. A similar effect is also seen in Figs. 1 and 2. The field is observed to be trapped inside the largest flute until the fourth camera frame of Fig. 2, that is about ½ μsec. after the first wedges become visible. In order for the diffusion time to be about ½ μsec., the electron temperature must be of the order of 5 × 10^5 °K.

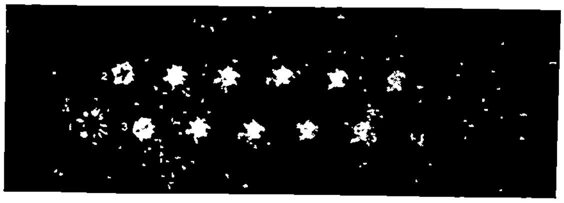

Fig. 1. Theta pinch with parallel magnetic fields. Ambient deuterium pressure 1 mm. mercury

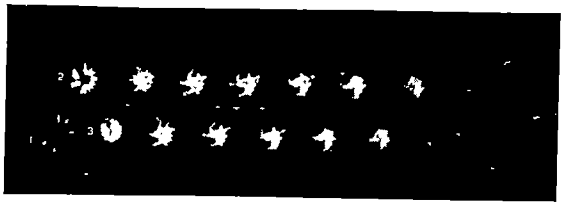

Fig. 2. Theta pinch with parallel magnetic fields. Ambient deuterium pressure 0·5 mm. mercury

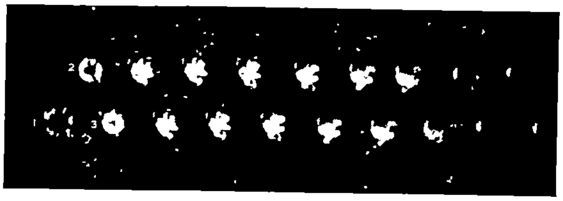

Fig. 3. Theta pinch with parallel magnetic fields. Ambient deuterium pressure 0·56 mm. mercury

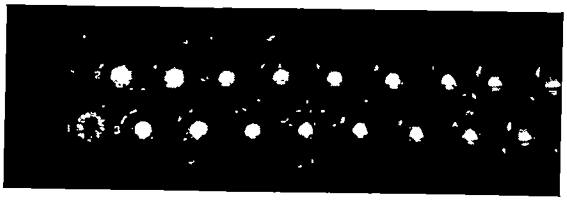

Fig. 4. *Prize* round ambient deuterium pressure 0·5 mm. mercury

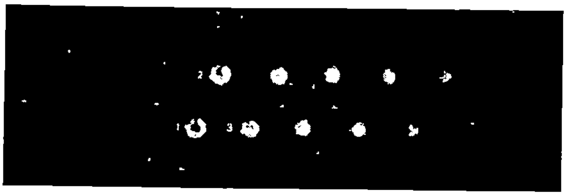

Fig. 5. Theta pinch with reversed trapped magnetic field. Ambient deuterium pressure 0·6 mm. mercury

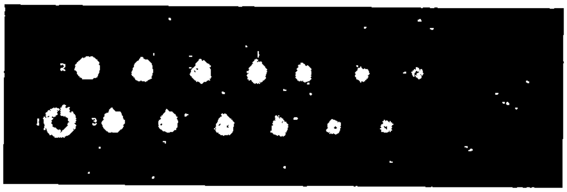

Fig. 6. Theta pinch with reversed trapped magnetic field. Ambient deuterium pressure 1 mm. mercury

The effect of reducing the trapped magnetic field by a considerable factor was studied by firing *Prize* with a 1 μF., 10 kV. condenser feeding the *z* pre-ionizer and a 40 μF., 10 kV. condenser bank feeding the theta pinch. Fig. 4 shows the result. It will be noticed that Rayleigh–Taylor type instabilities are formed during the implosion phase of the first half-cycle, but that they are damped out after the plasma converges on to the shock-tube axis; no outgoing flutes are observed after this time and better stability of the plasma is obtained.

Fig. 7. Schematic diagram of instabilities observed in theta pinches

The next step was obviously to produce a reversed trapped magnetic field during the first half-cycle of the discharge. This was done with a pair of Helmholtz coils placed adjacent to the theta piece and fed from a critically damped circuit so that the rise time of the external field was 3 μsec. and the maximum field produced was 1,000 œrsted. When the externally produced field was at a maximum the theta discharge was initiated and the plasma produced had a reversed trapped magnetic field. Figs. 5 and 6 show the effect of a reversed trapped magnetic field on the discharge; it will be observed that there are no radial wedges or Rayleigh–Taylor type instabilities and that there is only one gap in the otherwise continuous plasma cylinder. The gap in the plasma is adjacent to the power feed to the theta piece so that it may be ignored as a wedge effect. Since there are no apparent Rayleigh–Taylor instabilities in Figs. 5 and 6 we assume that the radial velocity of the plasma is constant and that the acceleration required for the growth of instabilities is only present for a very short time during the initial formation of the imploding cylindrical shock. If the current sheet had accelerated for a longer time we would have expected to see the same type of instabilities as those observed by Niblett and Green[1].

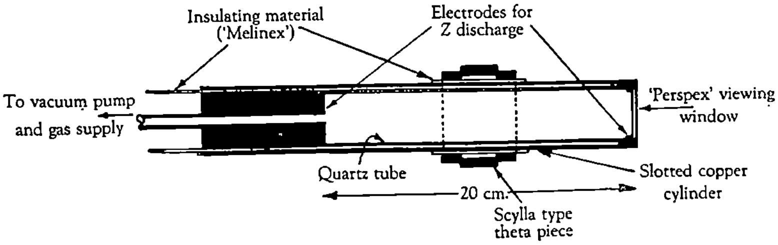

Fig. 8. Cross-section of *Prize*

Our experimental evidence suggests that the radial wedges are only formed when there is a trapped magnetic field in the same direction as the driving field, that is, when the azimuthal currents on the shock front and the current sheet have opposite directions of rotation. This hypothesis is also supported by the Niblett–Green[1] photographs, which show that radial 'wedges' are present when there is parallel trapped field. A possible reason for this is as follows: if the currents are in opposite directions Rayleigh–Taylor instabilities on the current sheet will produce flutes which can grow until they break up the plasma into radial wedges, each wedge carrying its own circulating current. The wedges travelling inwards at shock speeds produce bow waves which fill the interstices between the wedges with less highly ionized plasma. If the trapped field is in the opposite direction to the driving field the currents are in the same direction and the flutes produced by the instabilities in the current sheet are unable to break up the plasma, constrictions similar to the sausage type $m = 0$ instability observed by Josephson should then occur. An attempt to show the two effects graphically is made in Fig. 7.

Recent experiments on the *Scylla* apparatus[5], with the deuterium gas pre-ionized so that neutrons were observed in the first compression half-cycle, have shown that the neutron output was greatly enhanced by the inclusion, prior to the discharge, of a small axial magnetic field in the direction opposite to the compression field. We think there may be a connexion between this recent discovery and the instability mechanism discussed above.

We wish to thank Dr. R. Latham of the Imperial College of Science and Technology and Drs. H. R. Hulme and N. J. Phillips of the Atomic Weapons Research Establishment, Aldermaston, for stimulating discussions, and Messrs. A. Skinner and R. J. Abrey for the loan of their high-speed framing camera and their help and guidance in its use.

A NEW TEST FOR DETECTING ANAPHYLACTIC SENSITIVITY: THE BASOPHIL REACTION

By Prof. WALTER B. SHELLEY and LENNART JUHLIN*

Department of Dermatology, University of Pennsylvania School of Medicine Philadelphia

EACH year many individuals in seeming perfect health meet sudden death as a result of anaphylaxis. Such overwhelming allergic reactions reflect an immediate type hypersensitivity to diverse drugs, foods, insect bites or indeed even cold. Of all these, penicillin is perhaps the most common cause of anaphylactic shock and death. Although much is known of anaphylaxis, no safe reliable predictive test is yet available. Skin tests (direct, passive, and passive cutaneous anaphylaxis), serological antibody studies, as well as animal smooth muscle reactions each suffer serious limitations in clinical practice.

In our attempt to develop a test for anaphylactic reactors, two well-documented observations appeared to be of signal interest. First, all the key signs of anaphylaxis are, or may be, induced by histamine. Secondly, the depot of histamine in the blood is the basophilic granulocyte[1]. Thus, it seemed likely to us that in anaphylaxis the basophil might release its stores of histamine, with consequent degranulation similar to that observed in its congener, the mast cell[2]. Transmutation of this idea into experimental data has required two years for developing a technique to handle and to concentrate this at once fragile and rare white cell of the blood. We are now able to examine a miniature *in vitro* anaphylaxis system consisting of the human basophil, blood and antigen. Such work reveals the basophil to be a cell with a cytological picture reflecting its functional state. Hence it can serve as a laboratory index of anaphylactic sensitivities. The following is a preliminary account of our results.

---

* Present address: University Hospital, Uppsala.

The majority of these observations were made on twenty consecutive penicillin-sensitive patients and an appropriate twenty non-sensitive healthy control subjects. Limited investigations were also performed on four additional patients who had experienced severe systemic reactions to cold, bee stings and prochlorperazine. The following general sterile technique was employed. Tests were not made on subjects after a fat meal, during corticosteroid therapy, systemic illness, urticarial or anaphylactic reactions. At such times the basophils were often inadequate for testing purposes. Specimens of venous blood (0·25 ml., 5 μgm. heparin sodium added), drawn with siliconized needle and syringe, were mixed ('Vortex Jr.' mixer) with 0·025 ml. of penicillin or appropriate antigen in a concentration of 10^{-3} in physiological saline solution. After standing in a polystyrene tube at room temperature (25° C.) for 15 min., 0·1-ml. samples were withdrawn in siliconized syringes and added to ice-cold fixative solution (ethyl alcohol 6 ml., chloroform 2 ml., and acetone 2 ml.). After overnight fixation, at +4° C. the cells were re-suspended and aliquots were filtered through a cellulose membrane filter (Schleicher and Schuell, coarse 'Cella *O*', 20 min.). The filter was then selectively stained with toluidine blue (30 sec., 1/300 aqueous, phosphate buffer *p*H 5·2) dehydrated in ethyl alcohol and cleared in xylene. After mounting, the basophils could be clearly seen, counted, typed and photographed. Routinely a standard count of 20 consecutive basophils was made. The basophils were classified into distinct categories on the basis of size, staining properties, number and location of basophilic granules. Such a 'basophil differential' permitted accurate assessment of the effect of exposure to given antigens. In essence, the technique enabled us to distinguish the depleted from the intact cell. Depleted cells appeared as basophils (*a*) with few granules, or (*b*) with small lightly stained granules, or (*c*) with an appreciable number of granules seen outside the cell. The preparations were deemed unsatisfactory when the control slide showed more than one-fourth of the cells 'fired'. Our initial investigations suggest that for a positive test at least half the basophils exposed to the test antigen should show evidence of degranulation (depletion). It is apparent that test antigens must not be intrinsically 'histamine liberators' and must be used in concentrations which have no effect on the granulation of basophils in normal controls.

Table 1 reveals that each of the five patients with a history of penicillin anaphylaxis showed significant degranulation of the basophils in the presence of penicillin *in vitro*. It is important to note that the episodes of anaphylaxis predated the testing by months, even as long as nine years. Thus, anaphylactic penicillin sensitivity may be remarkably persistent. In the fifteen who gave a history of urticaria associated with penicillin (various types and routes of administrations, over a ten-year period), five had a positive test as defined by us. This urticarial group is heterogeneous. Some members may be sensitive to procaine or other substances, rather than penicillin. Others may have lost their sensitivity over the years, and, although re-administration of penicillin might re-light it, they are nevertheless non-sensitive at the time of our testing. None of the controls was positive. This is significant since these individuals had each had penicillin without any clinical reaction. Some were actually taking it at the time of testing. It would seem desirous to correlate further these results of predictive testing of penicillin sensitivity with the clinical administration of penicillin. This may be done in animal work, but not in man because of the potentially grave consequences. We can rely at present only on the close correlations of history and *in vitro* studies.

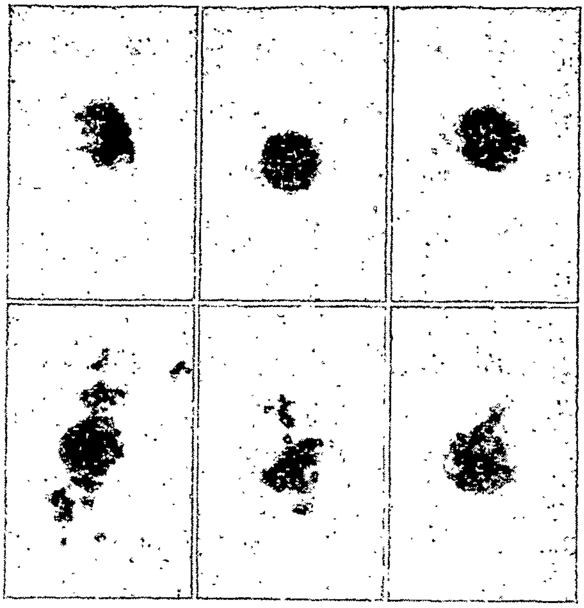

Fig. 1. Human basophils observed in an *in vitro* test for anaphylactic sensitivity. Upper three control cells show relatively intact structure. Lower three cells show varying degrees of explosive degranulation. The test is positive when more than 50 per cent of the cells show this depleted appearance after 15 min. exposure to test antigen in 10^{-4} concentration. (× 1,750)

Table 1 further shows that the results of the basophil test correlate well with the clinical histories of individuals who have experienced major or minor anaphylaxis as a result of immersion in cold water, yellow jacket bee sting, as well as another drug hypersensitivity, namely, prochlorperazine.

We feel that the test described aids in the detection of the anaphylaxis-prone individual. Nevertheless, negative data in this test reflect the patient's status only at the time of testing and do not anticipate any possible future sensitization. The test gauges the critical potential for anaphylaxis by determining the degree of anaphylactic sensitivity. Whether or not

Table 1

Clinical history	Antigen (10^{-4}) tested	No. of patients	Positive reactors
Penicillin anaphylaxis	Benzyl penicillin potassium	5	5
Penicillin urticaria (presumptive)	Benzyl penicillin potassium	15	5
Normals	Benzyl penicillin potassium	20	0
Cold anaphylaxis	+ 4° C. bath	2	2
Normals	+ 4° C. bath	10	0
Prochlorperazine urticaria	Prochlorperazine	1	1
Normals	Prochlorperazine	3	0
Yellow jacket Bee sting Anaphylaxis	Yellow jacket extract	2	2
Normals	Yellow jacket extract	2	0

a given patient actually experiences clinical anaphylaxis following antigen exposure rests on a large number of additional variables. The most important of these would seem to be the number of basophils and their histamine granule content at the time of exposure to the antigen. Even in the presence of a high degree of anaphylactic sensitivity, an antigen would not be expected to have much impact clinically if the basophil histamine load were light. Thus, the healthy, yet sensitized, adult with a full complement of loaded basophils is a prime candidate for anaphylaxis. Further work is in progress to learn more concerning the clinical significance of the rate of allergic basophil degranulation.

The parallel behaviour of the cutaneous mast cell in allergic reactions accounts for the development of urticaria. Here the histamine released has a local effect on the skin vasculature[3]. We suspect a high degree of correlation between the release of mast cell granules and basophil degranulation, but the dichotomy of the two systems may be apparent at times and thus account for negative skin tests in a known anaphylactic reactor.

'Basophil anaphylaxis' affords new cyto-immunological vistas since this target cell reaction can be observed in animals as well as in man. The data presented at least suggested that the basophil is the central cell of the anaphylactic state. It is hoped that the new technique described here will permit an intensive study of this heretofore elusive and labile cellular rarity of the blood stream.

This work was conducted under the sponsorship of the Commission on Cutaneous Diseases of the Armed Forces Epidemiological Board and was supported in part by the Surgeon General, Department of the Army, and in part by grant *PHS 2G*-62 from the National Institutes of Health.

STEROIDS AS ICE NUCLEATORS

By RICHARD B. HEAD

Commonwealth Scientific and Industrial Research Organization,
Chemical Research Laboratories, Melbourne

MOST substances suggested as possible ice nuclei for cloud seeding are inorganic compounds of hexagonal structure with lattice parameters similar to those of ice. The possibility of using organic compounds as ice nuclei has not yet been explored. During an investigation of water-insoluble organic compounds, seven out of thirty steroids examined, the symmetry of which was mainly monoclinic or orthorhombic, were found to nucleate ice almost as effectively as silver iodide. The discovery of a class of organic materials capable of acting as ice nuclei appears to be novel.

Activities were determined by means of a microscope cold stage into which slides carrying steroid particles could be inserted. Provision was made for the introduction of moist air. The particles under test thus acted as freezing nuclei.

Although nucleations occurred on a proportion of crystals slowly grown from alcohol, as shown in Fig. 1 (androstenolone at −12° C.), none occurred on small needles or plates grown rapidly. Particularly active sites were engendered by quick recrystallization

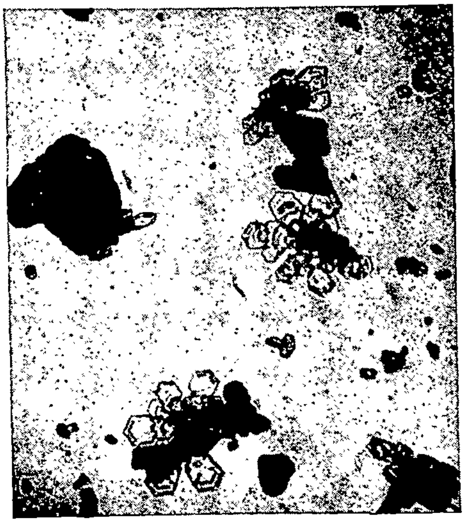

Fig. 1. Ice crystals growing on androstenolone at −12° C.

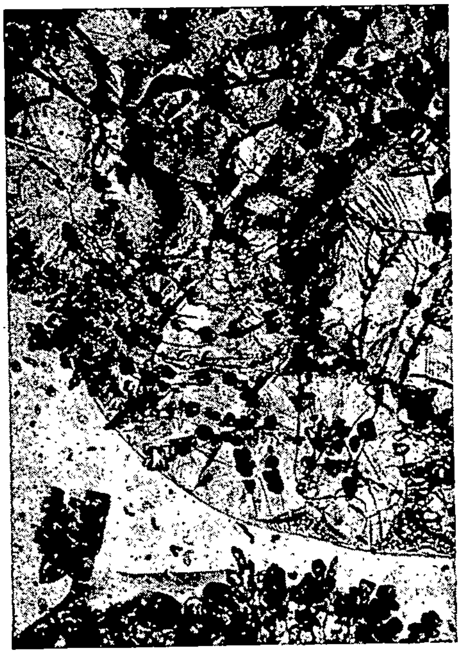

Fig. 2. A recrystallized droplet of androstenolone showing multiple nucleations on cracks

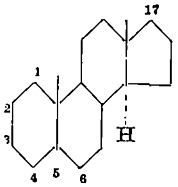
at the melting point in air or pure nitrogen, followed by quick cooling. This was done by heating a slide, powdered with crystals, at one end until about half the particles had melted. A line of particles which had recrystallized near the melting point was thus formed at the junction of the melted and unmelted portions, and these, together with the larger droplets which had recrystallized on cooling, showed multiple nucleations, especially at cracks. Fig. 2 shows part of a recrystallized droplet of androstenolone on which more than a hundred nucleations occurred at −7° C. Droplets smaller than about 0·03 mm. diameter were usually inactive.

The most active steroids were androstenolone (I), testosterone (II), 3α-methylcholestan-3β-ol (III), androsterone (IV), pregnenolone (V), androstan-3,17-dione (VI), and cholesterol (VII), for which the onset temperature was −5° C. Nucleation of all particles larger than 0·03 mm. diameter was complete at −7° C.



Compound	Position of C=C	Configuration at position 5	Substituent at C_3	Substituent at C_{17}
I	5–6	—	β-OH	=O
II	4–5	—	=O	β-OH
III	—	5α-H	αMe-β-OH	β-C_8H_{17}
IV	—	5α-H	α-OH	=O
V	5–6	—	β-OH	β-$COCH_3$
VI	—	5α-H	=O	=O
VII	5–6	—	β-OH	β-C_8H_{17}

Much lower activities were shown by androsta-1,4-dien-3,17-dione, cortisone, cholestenone, progesterone and œstrone, while no activity was shown by steroid esters, ergosterol, 17α-methyltesterone or 3β-methylcholestan-3α-ol, although the 3β-ol compound was very active. Substances with no groups capable of hydrogen bonding such as 3β-methylcholestane were inactive.

It is usual to associate nucleation with the similarity in spacing between the ice lattice and that of the nucleating substance. The exact crystal structures of many steroids are still unknown; but the survey by Bernal, Crowfoot and Fankuchen[1], and the detailed analyses of cholesteryl iodide[2], and lanostenyl iodoacetate[3], suggest that the molecules in the majority of steroidal structures are arranged in parallel stacks with 'head-to-tail' packing. One surface of the stack would thus present a pattern of alternating hydroxy groups and side-chains. It is presumed that nucleation takes place on this surface. The relationship between the cell dimensions of ice and those of the steroids is not obvious, but the cross-sectional dimensions of the steroid molecule, 5 ± 1 Å. × 7 ± 1 Å., deduced by Bernal *et al.*[1] suggest a possible compatibility with the prism face of ice (4·51 Å. × 7·35 Å.) although it is realized that this spacing is only relevant if the molecules are stacked approximately normal to the surface. The precise measure, however, would depend on the structural dimensions of the crystal form.

It has been shown that the most active substances have keto or hydroxy groups at position 3, and it is notable that three of them have keto groups at position 17 in addition. That these groups may be interchanged without loss of activity is illustrated by the comparison of androsterone versus testosterone. If it is assumed that the essential requirement for activity is a hydroxy or keto group at position 3, it is clear why no activity is shown by the steroid esters since esterification occurs at this position. The failure of 3β-methylcholestan-3α-ol and 17α-methyltestosterone to show activity is probably due to the shielding of axial hydroxy-groups by equatorial methyl groups.

It is interesting to find a class of compounds in which the presence of nucleation sites depends so much on the physical methods of sample preparation. The most active samples of cholesterol prepared appear to contain robust sites which will withstand radiation equivalent to a 100 min. of sunlight without losing activity. This may be due to the inaccessibility of other positions of attack if only the edges of the molecular stack are exposed.

IDENTITY OF L-ASCORBIC ACID FORMED FROM D-GLUCOSE BY THE STRAWBERRY (*FRAGARIA*)

By Dr. FRANK A. LOEWUS and STANLEY KELLY

Western Regional Research Laboratory*, Albany 10, California

WORK in this Laboratory has shown that ascorbic acid recovered from ripening strawberries or germinating cress seedlings administered D-glucose-1-^{14}C is labelled primarily in carbon 1 (the carboxyl carbon)[1,2]. In these experiments, ascorbic acid was removed from the plant extract with an ion exchange resin, 'Dowex 1-formate', selectively eluted by means of a formic acid gradient, diluted with non-isotopic L-ascorbic acid, recrystallized from methanol and ethyl ether mixtures or from glacial acetic acid until there was little or no change in specific activity, and, finally, degraded chemically to determine the specific sites of ^{14}C labelling. A portion of the ^{14}C-containing ascorbic acid plus carrier L-ascorbic acid was oxidized with *p*-quinone to dehydroascorbic acid and then converted to its di-*o*-phenylenediamine derivative[3]. The free acid of this derivative, crystallized from water, had the same specific activity as the ascorbic acid. Conversion of this free acid to its lactone and recrystallization from methanol also yielded a product with the same activity.

---

* A laboratory of the Western Utilization and Research Division, Agricultural Research Service, United States Department of Agriculture.

When these results were published it was felt that these observations sufficed to establish the exact isomeric nature of the labelled ascorbic acid from the strawberry or the cress seedling as L-ascorbic acid. However, Takahashi, Mitsumoto and Kayamori recently published two notes[4] describing the formation of D-araboascorbic acid (D-*iso*ascorbic acid) by various species of the mould, *Penicillium*, when it was grown on D-glucose, D-gluconic acid or sucrose. They also found that *P. notatum* converted D-glucose-1-^{14}C to D-araboascorbic acid in which 80 per cent of the ^{14}C of the molecule was located in carbon 1. The discovery that *Penicillium* can convert D-glucose to D-araboascorbic acid suggests that a more critical appraisal should be made of the isomeric nature of ascorbic acid recovered from higher plants which have been administered specifically labelled D-glucose-^{14}C.

This communication presents the results of an experiment designed to compare L-ascorbic acid and D-araboascorbic acid as carrier substances in the successive recrystallization of labelled ascorbic acid obtained from a ripening strawberry administered D-glucose-6-^{14}C. D-Glucose-6-^{14}C (50 μc. at 7·7 mc./m.mole) was administered in 0·1 ml. of water through the cut stem of a strawberry in the green–white stage of ripening. It required 3 hr. for the aqueous solution to be taken up by the strawberry. After an additional 40 hr. with the stem immersed in distilled water, the fruit (less hull and stem) was frozen, mascerated in ethanol at − 40° and the ascorbic acid recovered without carrier dilution on a 'Dowex 1-formate' exchange resin. The ascorbic acid was selectively eluted with a gradient of 0 → 0·06 *N* formic acid and the fractions containing ascorbic acid, as characterized by titration of aliquots with 2,6-dichlorophenol indophenol, were pooled. These pooled fractions, which contained 5·6 mgm. of reducing material, were divided into two equal portions. To one was added 200 mgm. of D-araboascorbic acid and to the other, 200 mgm. of L-ascorbic acid. Each was evaporated to a syrup, taken up in glacial acetic acid and allowed to crystallize in the cold. Subsequent crystallizations were also done in glacial acetic acid. The radioactivities of each series of crystallizations are summarized in Table 1. With L-ascorbic acid as the carrier, the product after three crystallizations was only slightly less active than after the first crystallization. By contrast, nearly all the carbon-14 remained in the mother liquor when D-araboascorbic acid was used as a carrier. Less than 2 per cent of the specific activity found in the portion diluted with L-ascorbic acid was retained in the portion diluted with D-araboascorbic acid.

The identity of labelled ascorbic acid as L-ascorbic acid was also confirmed by preparing two derivatives of the product representing the third crystallization of the L-ascorbic acid-diluted portion and by comparing their activities with the original ascorbic acid. Both derivatives had specific activities similar to the ascorbic acid used in their preparation (Table 1). Derivatives of the carrier L-ascorbic acid and D-araboascorbic acid were also prepared and submitted to microanalysis.

The 5,6-*iso*propylidene L-ascorbic acid was prepared by the method of von Vargha[5] and recrystallized from absolute ethanol. Calculated for $C_9H_{12}O_6$: C, 50·0 per cent; H, 5·60 per cent. Found: C, 50·1 per cent; H, 5·67 per cent. Attempts to prepare 5,6-*iso*propylidene D-araboascorbic acid by the same procedure resulted in a product having the same melting-point and elemental analysis as D-araboascorbic acid and showing no melting-point depression when mixed with authentic D-araboascorbic acid. Calculated for $C_6H_8O_6$: C, 40·9 per cent; H, 4·57 per cent. Found: C, 41·0 per cent; H, 4·71 per cent. Apparently, the conditions sufficient for the formation of 5,6-*iso*propylidene L-ascorbic acid cannot effect the formation of 5,6-*iso*propylidene D-araboascorbic acid.

Table 1. RADIOACTIVITY OF CARRIER-DILUTED ASCORBIC ACID FROM A STRAWBERRY LABELLED WITH D-GLUCOSE-6-^{14}C

Diluent	L-Ascorbic acid		D-Araboascorbic acid	
	Amount recovered (mgm.)	Radioactivity, mμc./mmole of ascorbic acid	Amount recovered (mgm.)	Radioactivity, mμc./mmole of ascorbic acid
First crystallization	155	74·7	97	8·2
Second crystallization	99	68·7	79	2·0
Third crystallization				
First crop	48	66·5	56	1·0
Second crop	12	69·2		
5,6-*Iso*propylidene derivative		57·4*		
2,3-Diphenacyl derivative		64·2*		

* Activities corrected for a 5·76-fold dilution in the case of the diphenacyl derivative and an 11·7-fold dilution in the case of the *iso*propylidene derivative. These derivatives were wet combusted with Van Slyke–Folch reagent to carbon dioxide and counted in an internal gas phase proportional counter (ref. 14). Other activities were determined in a liquid scintillation apparatus using a liquid scintillation mixture of 0·6 gm. naphthalene, 14·5 ml. *p*-dioxane containing 0·4 per cent 2,5-diphenyloxazole and 0·01 per cent 1,4-*bis*-2(5-phenyloxazolyl)-benzene and the radioactive ascorbic acid in 0·5 ml. of water (ref. 15).

A second derivative, 2,3-diphenacyl L-ascorbic acid[6], was prepared according to the same procedure used to obtain diphenacyl malate[7]. The crude, moist, crystalline product was recrystallized immediately from ethanol in order to avoid the partial decomposition otherwise observed. Calculated for $C_{22}H_{20}O_8$: C, 64·1 per cent; H, 4·88 per cent. Found, L-isomer: C, 64·1 per cent; H, 5·02 per cent. M.p. 137–138°. D-isomer: C, 63·2 per cent; H, 4·99 per cent. M.p. 139–140°.

A portion of the recrystallized L-ascorbic acid diluted fraction was further diluted with authentic L-ascorbic acid (non-isotopic) and degraded[8,9], and the carbon-14 distribution results are given in Table 2. This pattern confirms one obtained previously from a strawberry labelled with D-glucose-6-^{14}C (ref. 10),

Table 2. DISTRIBUTION OF CARBON-14 IN L-ASCORBIC ACID-DILUTED PORTION AFTER THREE CRYSTALLIZATIONS

	Radioactivity*		Total ^{14}C (per cent)
	mμc./m.mole of carbon	mμc./m.mole of ascorbic acid	
Carbon 1 + 2	6·14	12·28	18
Carbon 3	5·25	5·25	8
Carbon 4 + 5	0·86	1·72	3
Carbon 6	47·18	47·18	71
Sum of degraded fragments		66·43	
Van Slyke–Folch wet combustion	11·08	66·48	

* Activities of the degraded fragments are corrected for a final 5·35-fold dilution of L-ascorbic acid after the third crystallization. All counting data were obtained with an internal gas phase proportional counter (ref. 14).

but more importantly, it provides a definitive reply to suggestions[11,12] that such a pattern could also be obtained if D-glucose-6-^{14}C were converted by two separate pathways to a mixture of L-ascorbic acid (labelled primarily in carbon 1) and D-araboascorbic acid (labelled primarily in carbon 6). The present results show that 71 per cent of the carbon-14 in the L-ascorbic acid remained in carbon 6, whereas the residual activity found in the D-araboascorbic acid after two recrystallizations may have been due to traces of L-ascorbic acid.

It may be concluded from this brief study that higher plants do contain an enzymic process capable of converting D-glucose to L-ascorbic acid over a pathway which preserves the carbon skeleton and does not invert the carbon chain yet does result in an epimerization at carbon 5 from the D to the L configuration. Tracer work on ascorbic acid biosynthesis in plants preceding the experiment just described has been reviewed in a paper that will be published shortly[13].

We acknowledge the help of Miss Geraldine Secor, who performed the microanalyses, and the suggestions of Dr. Peter Dayton, Goldwater Memorial Hospital, New York, concerning the preparation of 5,6-*iso*propylidene L-ascorbic acid.

AMINO-ACID LIBERATION FROM PROTEINS BY ENZYME OR 'HEAT CATALYSED' HYDROLYSIS

By S. M. HARDY*

Research No. 5, The Hospital for Sick Children, Great Ormond Street, London, W.C.1

THE term 'heat catalysed' hydrolysis is introduced here for the first time to emphasize a certain phenomenon in the so-called acid/alkali hydrolysis of proteins which has been overlooked apparently or underestimated hitherto. The term is used to point out some interesting similarities between acid/alkali and enzymic hydrolysis, such as the similar parts played by the enzyme and by the heat in bringing about the liberation of amino-acid from the peptide chain. At the same time certain dissimilarities between the two processes will be indicated, and it will be shown how these may explain the significant differences in the physical parameters of the resultant amino-acids.

Analysis of urinary peptide and amino-acid excretion in children has been carried out recently using a high-tension electrophoretic apparatus which I have designed and constructed. This was of the free-floating type. It was kept at a constant temperature of 0° C. by a refrigerated *n*-hexane circulating system controlled by thermistors. The cooling was efficient enough to maintain the entire length of the electrophoretic paper at within 0·5 deg. C. of the same temperature. This was checked by the use of a series of ten specially designed thermometers which were placed in contact with the paper at 10-cm. intervals. Thus the temperature of the paper was measured throughout the entire operation.

Whatman No. 4 paper 1 cm. wide and 120 cm. in length was used. The paper was suspended horizontally through the centre of the cooling liquid with the nylon-sheathed ends dipping into the two buffer-electrode containers. The buffer used had a pH of 1·9 (acetic acid–formic acid–water, 3 : 1 : 16) with a conductivity of $0·3 \times 10^4$ micro-ohm. The power used was 200 V./cm. length of paper and thus 1·0 m.amp./cm. width of paper for 25 min. was produced. While this was taking place several hitherto undescribed phenomena in the behaviour of amino-acids at high field strengths were observed.

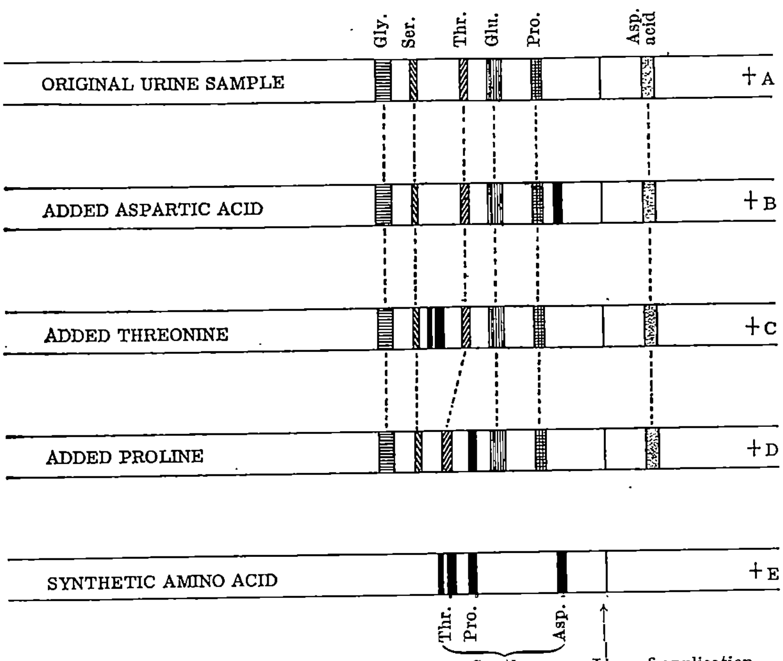
Among these was one which initially caused some difficulties, when it was attempted to identify the separated fractions by adding, to the ion-exchange resin-desalted urinary sample, commercial amino-acids of high purity which were known by previous chromatographic tests to be present in the urinary sample. The result was that these added amino-acids, instead of joining up with their urinary counterparts, and thus increasing the intensity of the subsequent colour reaction, produced separate additional fractions on their own.

The findings of an experiment in which three commercial amino-acids were added to the ion-exchange resin-desalted urinary sample are demonstrated in Fig. 1. The original urine of a healthy child yielded, according to previous chromatographic evidence, six amino-acids in ninhydrin-staining quantities; the same six amino-acids were also found to be separated on subsequent high-tension electrophoretic testing. Strip *A* represents the urinary sample, yielding aspartic acid, proline, glutamic acid, threonine, serine and glycine. On strips *B*, *C* and *D*, aspartic acid, threonine and proline were added to the urinary sample respectively. Finally, on strip *E* all three commercial amino-acids that were added can be seen in a simple buffer solution alone.

It is apparent that in no case have the added amino-acids joined up with their urinary counterparts. They have produced instead an additional fraction on their own account which is clearly identifiable.

---

* Present address: Department of Biochemistry, Dulwich Hospital, East Dulwich Grove, London, S.E.22.



200 V./cm. 1 m.amp. pH 1·9. 25 min.

Fig. 1

(Threonine has produced not one, but two fractions on strip *C*, as well as on strip *E*. This is thought to be due to the fact that this amino-acid is a racemic mixture of D- and L-threonines. This particular finding and the possible explanation for it will be discussed separately in a later paper.)

This test was repeated chromatographically, but no such behaviour was then observed. The commercial amino-acids which were added merely joined up and increased the ninhydrin colour reaction of the appropriate amino-acids.

After repeating these tests and obtaining the same results, it was concluded that the underlying explanation for this specific and unexpected behaviour must lie in the electric parameters of the respective amino-acids, since it was found to manifest itself only when they were subjected to a strong electric field.

The major factor determining the mobility of amino-acids in electric fields is the molecular electric charge of the amino-acid itself. It is assumed, therefore, from the findings described here that the molecular electric charge of urinary and commercial amino-acids must differ.

The literature has been searched for descriptions of similar experiences by others using high-tension electrophoretic techniques. It was found that the actual number of authors who describe their results in detail using various means of chemical identification of the separated fractions is very small, and that those who do so do not mention such difficulties as have just been described.

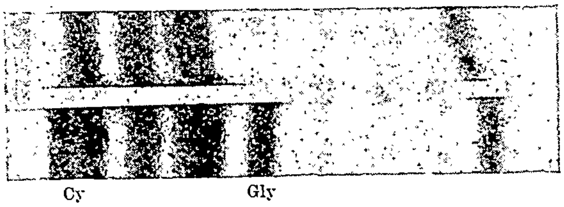


Fig. 2

In one single instance, however, in an article by Heilmeyer *et al.*[1], a photograph of an original high-tension electropherogram was found (Fig. 2). This illustration (Fig. 3 of the original article) shows two stained high-tension electropherograms. On the upper strip four amino-acids separated from the resin-desalted urine sample can be seen. Underneath is another strip, on which it can be seen that the actual number of separated fractions has increased by two. The caption states that in the case of the lower strip two commercial amino-acids, cysteine and glycine, have been added (these are marked Cy and Gly). However, there is no mention, in either the text or caption, of the fact that the number of separated fractions has increased. This increase in this case is thought to be a confirmation of my own findings.

The importance of this specific behaviour of amino-acids, the fundamental building blocks of proteins, in electric fields will become more evident if we consider that, in biological circumstances in living systems, proteins, peptides and amino-acids, as well of course as other metabolites, are under the permanent stress of electric fields applied across biological membranes. These electric fields are maintained by the difference in concentration of the electrolytes on the two sides of the membrane, and they amount to an average potential difference of 100 mV. Since the average thickness of such membranes is of the order of 10^{-6} cm., the average actual value of these biological membrane potentials is of the order of 100,000 V./cm. Thus it can be said that the electric field maintained by my high tension electrophoresis is somewhat sub-biological, being about a tenth of the average of the living cell. These biological potentials, however, are characteristic and inherent parts of the living systems and their changes are the foundations of life.

The importance of this biological electrical field has already been emphasized in a previous report[3]. Attention was directed to the fact that there may be a selective biological membrane transport of individual amino-acids due to these biological potentials.

It would therefore seem important to try to elucidate the real foundations of this unexpected behaviour of amino-acids derived from different modes of liberation.

Living organisms liberate these amino-acid metabolites from food proteins by the use of enzymes at the average body temperature of the living species. The amino-acids that are commercially available, on the other hand, are either liberated by acid/alkali or enzymatic hydrolysis of a readily hydrolysable protein, for example, casein, or else are the result of bacterial metabolic production. It was thought that a closer investigation of at least the two main types of liberating processes—the acid/alkali and the enzymic—might provide some explanation as to why commercial amino-acids bear a different molecular electric charge from their urinary counterparts.

In the enzymic hydrolysis of proteins, the protein substrate is first subjected to an adjustment of its original *p*H. This will be according to the optimum range of *p*H for the enzyme(s) to be used. This imposed change of *p*H can be either on the acid or on the alkali side. The importance of this *p*H adjustment is obvious from theoretical considerations, and it was assumed earlier that the carriers of catalytic activity of enzymes were mostly the zwitterionic forms of the molecule, since it was observed that in most cases the optimum *p*H coincided with the isoelectric point of the enzyme. This was first suggested by Michaelis and Davidsohn[4], but since then it has been discovered that this is often not the case, and the isoelectric point does not really coincide with the optimum *p*H; therefore, it is supposed that the activity is dependent on the ionization of certain groups on the enzyme molecule and not always necessarily in the zwitterionic form.

The importance of the effect of *p*H on enzymic activity from the point of view of the quality of hydrolysis is laid down in an excellent work by Wilson and Nachmanson[5], in which they elucidated the reaction mechanism of the acetylcholinesterase enzyme. Waley[6] and Dixon[7] have demonstrated the effect of *p*H in general on enzymic activity.

After the adjustment of the *p*H of the protein substrate, the chosen enzyme(s) is introduced, and at the optimum temperature, the process of enzymatic hydrolysis proceeds.

Since it is proposed to deal later on with the heat-catalysed acid/alkali hydrolysis of proteins, it is thought that the meaning of the term 'optimum temperature' should be looked at more closely. Temperature is surely one of the most influential and important factors governing reaction mechanisms specificially in biological processes. The optimum temperature is generally considered to be the deg. C. at which the maximum rate of reaction occurs, or in other words, at which the enzyme will liberate the greatest number of amino-acids from the protein substrate in a given time. As early as 1895, Tammann[8] suggested that enzymic processes show acceleration when the temperature is raised, but when a maximum point has been reached will slow down rapidly again on account of thermal destruction of the enzyme protein molecule itself, in which case irreversible changes take place in the molecular configuration of the enzyme which greatly affect its specific activity, and finally arrest it. It will be seen that this optimum temperature is a range of temperatures rather than a sharp point, since living systems are accustomed to certain degrees of change in their environmental temperature, which in turn influence their internal temperature; thus, their metabolic processes have acquired, during the course of evolution, a certain flexibility in their response to changes in temperature over a limited range. It is important to maintain the optimum temperature in enzymic processes, because if it falls or rises the inherent energy content of the reactive system would be either reduced or increased, thus causing variation in an important factor in the reaction mechanism.

It can be said with certainty at this stage that in enzymic hydrolysis, whether *in vitro* or *in vivo*, change of entropy does not occur appreciably; no mass resonance, rotation, translation or vibration of the electron system of the reacting molecules occurs and the force binding the enzyme to the substrate protein molecule acts by straightforward contact and is dependent among others on intermolecular distances. Charged groups on the substrate molecules become attached to groups on the enzyme molecules bearing opposite charges. This bond may be analogous to 'salt-bridge' formation in proteins. It is known that the K_S (dissociation constant of the enzyme-substrate complex) is infinite only for positively charged substrates of trypsin. Hydrogen bridges may also play a part. Protein molecules are capable of forming intramolecular hydrogen bridges, and with a suitable substrate it is plausible that intermolecular hydrogen bridges can also be formed. This is thought to be the case with the proteases. Van der Waals forces also come into play, for example, in the action of cholinesterase, where the K_S decreases and therefore the affinity increases with the increasing length of the hydrocarbon chain in the acyl esters of choline. Finally, it should be mentioned that the substrate can also react with the enzyme in the formation of covalent bonds.

In all these types of enzymic hydrolysis reactions the reacting substrate protein molecules utilize their molecular free-energy content, for no external energy is supplied to them in any form; the maintenance of a constant optimum temperature prevents them from losing energy unproductively.

It is also well known that enzymic hydrolysis of proteins can be repeated successfully with the same results so long as the delicate experimental conditions are adhered to strictly. The specific mode of action of the various enzymes has been described and explained by Neurath and Schwert[9], Smith[10] and Green and Neurath[11].

In the heat-catalysed hydrolysis of proteins the substrate protein undergoes the same preliminary treatment as in the enzymic process described above, namely, its *p*H is changed. But in this case, instead of introducing the enzyme into the *p*H-adjusted substrate, external energy is supplied in the form of excessive heat, and thus amino-acid liberation occurs.

A well-known phenomenon in chemistry is the increase in the rate of reaction which occurs when the temperature of the reactive mixture is raised. This increase cannot be accounted for solely by the increased number of molecular collisions because, as a rule, the rate of the reaction increases with the rising temperature far more sharply than does the frequency of the collisions. It will be remembered that reacting molecules having an average velocity do not generally produce chemical reactions since they do not have enough energy to develop into the transitional state. This transitional state, from the point of view of energy consumption in reactive phases, is the top of a curve up which the reacting molecules must have sufficient energy to climb before they can descend down the other side, releasing energy and forming the product. The rate of reaction is related then to the number of molecules that pass from the reactive side to the productive side of this curve in a given time. Raising the temperature will necessarily increase the number of molecules with sufficient energy to take part in this process.

The thermodynamic constants, for example, heat, entropy, etc., of activation and reaction supply a good picture of the stages of reaction in these cases. Kunitz[12] has provided evidence for the reversible denaturation by heat of crystalline trypsin inhibitor, a globular protein of 25,000 mol. wt. He found that when the native protein was denatured reversibly, the heat generated by the reaction was 57·3 k.cal./mole and the entropy change was 180 cal./°C./mole. There was a great increase in entropy and no increase in the number of molecules in the substrate heated.

This indicates that the denatured form of the molecule is formed from the native state by bond breakage, and thus it has greater freedom of movement than before. It is an interesting point that the total energy of the activated complex is almost the same as that of the denatured form and very different from that of the native form.

This activated complex is an intermediate form of the native molecule in its progression to the end product and its lifetime is about 10^{-13} sec. Once formed, it decomposes with a frequency of kT/h, where T is the absolute temperature, h is Planck's constant and k is Boltzmann's constant, that is, R/N the gas constant per molecule. The precise significance of the activated complex, however, can only be appreciated by extensive reference to the quantum theory and statistical methods, subjects which it is not intended to develop further here.

However, the entropy of the activated complex is still much less than that of the total completed reaction, that is, the sum of the entropies of the amino-acids liberated. Under the compelling influence of the constantly available supply of excess energy the activated protein molecule, while not gaining in its molecular free-energy content, steadily increases its entropy until such a state of instability is produced that some of its valence bonds will be broken. The remaining bonds will break spontaneously as time progresses.

It is reasonable to assume that the excess energy in the activated protein complex at the time of its final break-up will reside in the resultant amino-acids.

It has been found by Eyring and Stearn[13] using trypsin, and by Eisenberg and Schwert[14] using chymotrypsin, that the value of the thermodynamic constants of heat denaturation of proteins depends significantly on the pH of the substrate. This is interesting if it is considered together with the dependence of pH of the enzymic activity.

The fact that it has many drawbacks is a well-known characteristic of such a heat-catalysed liberation of amino-acids. These include structural modification, racemization, tautomerization, destruction and artefact production of various types of amino-acids, as have been described by Neuberger[15], Spies and Chambers[16], Dakin[17], Levene and Steiger[18], and Sanger and Thompson[19]. These authors are all in agreement, and they suggest that such amino-acids as are formed during heat-catalysed hydrolysis of proteins are chemically and biologically identical to those liberated by enzymatic hydrolysis. They admit that side-effects are unavoidable, and although they are to some extent undesirable, they account merely for some quantitative and qualitative loss or gain of some specifically known amino-acid.

In attempting to find the fundamental difference between enzymic hydrolysis or enzyme-catalysed hydrolysis and acid/alkali hydrolysis or heat-catalysed hydrolysis, it becomes apparent that it is to be looked for in the very similarity of the two methods. The two kinds of liberating agents, the heat and the enzyme, both produce the same result, namely, bringing about breakage of the terminal bonds of amino-acids: without them there would be no significant liberation of amino-acids. But if we go one step further and consider the way in which these two agents, to such an extent similar, achieve their final target, we must realize the essential dissimilarity between their activities.

What kind of factor is it then which can be pointed out as responsible for the dissimilarities in the molecular electric charges of the liberated amino-acids, since they are chemically and probably, so far as we know at present, biologically identical ? It is unlikely to be found in the similarities between the two methods. But in considering the differences between them, in terms of the utilization of energy, exchange of energy and the general relations between the energies involved in the processes, the real cause may be brought to light.

In enzymic processes, as I have already pointed out, there is no need whatever to provide energy externally, as there is in heat-catalysed hydrolysis. All the energy needed to proceed from one side of the 'hill' over the 'summit' of the intermediate complex to the resultant reactive side of the liberated amino-acids is obtained from the molecular free-energy content of the protein substrate itself, and of the enzyme without significant change in the entropy of the system and well within the limits of thermodynamics. This is why any kind of gross structural irregularity, artefact production or destruction of amino-acids during enzymic hydrolysis would not be expected. Everything proceeds along a fairly well-determined pathway in stages which can to some extent be calculated from the thermodynamic equations.

But this is not the case in heat-catalysed hydrolysis. In this method of liberation of amino-acids, excess energy is transferred to the protein substrate. An unlimited amount of energy is available for any type of energy-consuming reaction to take place. The intra- and inter-molecular bonding electrons of the protein substrate molecules are also excited by means of resonance to extreme levels. The heat energy is absorbed by the electron system and transformed into electrical form. The molecular electric charge of the resultant amino-acid ultimately depends on the behaviour of the electron pool. These electric effects are not great enough to cause alternations in the chemical behaviour of the molecules; but the physical means by which they are recognized, their molecular electric charge, is altered sufficiently to change their motility in an electric field, and thus make them behave differently from the chemically similar amino-acids formed by the enzymic liberating processes.

If this problem is considered more in terms of physics than of chemistry, it will be seen that the application of wave mechanics to the behaviour of electrons will lead to an understanding of the function of the ultra-structure of the living intracellular system, and to an appreciation of factors hitherto thought to be insignificant.

It is suggested therefore that, under the readily observable chemical changes in heat-catalysed hydrolysis, there lie appreciable variations in the world of physical parameters. There are a number of changes in the physical nature of the molecules which may occur, but which will not affect necessarily the simple chemical behaviour of the amino-acids. They will, however, become apparent when tested by sufficiently sensitive methods, for example, that of molecular electric charge measurement.

Unfortunately, it was beyond the scope of the present research to investigate the demonstration of the differences in molecular electric charge by physical means other than high-tension electrophoresis.

However, it is thought to be more than probable from what is known of the forces involved in crystallization, that the existence of differences in molecular electric charge on one or two sites of an amino-acid molecule would result in alteration, if only to a limited extent, of its crystalline structure. Nevertheless, I have been unable to find any reference in the literature to work on the crystalline structures of amino-acids derived from different means of liberation.

Another means by which it would apparently be possible to prove or disprove the above theory would be to measure the electron spin resonance of these differently liberated amino-acids. This excellent method, although in its pioneer stage, promises to become a most powerful tool for fundamental research, and is already finding its way into biological laboratories at the present time[20,21].

The measurement of the diamagnetic susceptibility of amino-acids[22] of different origin would also be a useful method of investigation. In 1936, Bauer and Ruskin[23] used this method with great success in establishing the differences between the diamagnetic susceptibility of proteins in living and non-living states. Work along similar lines is in progress, to interpret their results in the light of the present findings with regard to molecular electric charge and its connexion with the electrical functions of living systems, and will be described later in a separate publication.

I thank G. H. Zeal and Co., London, for their help in designing and supplying special thermometers for the observation of temperature variations along the entire length of the high-tension electrophoresis paper. This has enabled me to clear up an important point and one which has been in question for many years.

BIO-ASSAY OF ERYTHROPOIETIN IN MICE MADE POLYCYTHÆMIC BY EXPOSURE TO AIR AT A REDUCED PRESSURE

By Dr. P. MARY COTES[*]

Medical Unit, University College Hospital Medical School, London

AND

Dr. D. R. BANGHAM

National Institute for Medical Research, London

ERYTHROPOIETIN is characterized by its ability to induce an increase in the total red cell mass of an intact normal animal[1]. This property is seldom used for the estimation of erythropoietic activity in biological fluids from individual animals or human subjects, since it requires larger amounts of active material than are usually available. For this reason, methods of assay in common use employ test animals in which red cell formation has been suppressed[2,3] so that there is a low base-line from which to measure stimulation of erythropoiesis. Formation of new red cells is estimated by measurement of parameters which reflect maturation and division of bone marrow cells[4], hæmoglobin synthesis[5–7], or a mixture of these events. The assays in most general use are based on measurement of reticulocyte counts[8–12] or incorporation of iron-59 into circulating red cells[5–7]; the test animals are normal[10,11] or starved[3,5] or transfused-polycythæmic rats[7] or mice[8]. This article describes a system for the bio-assay of erythropoietin in mice in which endogenous red cell formation is suppressed by the polycythæmia which persists after animals have been exposed to air at a reduced pressure; incorporation of iron-59 into red cells is used as the response parameter to measure the stimulation of new red cell formation produced by the administration of exogenous erythropoietin.

The erythropoietin used in development and use of the assay was prepared from plasma of rabbits, monkeys or sheep, made anæmic by treatment with phenylhydrazine. The rabbit material was a filtrate made from plasma after heat treatment at *p*H 5·5 essentially as described by Borsook[13]; it was stored at − 30° C. The monkey material was prepared from the supernatant of plasma after treatment with 15 per cent w/v sodium sulphate. The sheep material was a freeze-dried powder (Lot No. *RO*77019), purified in the Armour Laboratories and kindly provided by Dr. White; it was made up in solution so that 1 ml. contained 8·0 'cobalt units'[14]. The human erythropoietin was unfractionated plasma from an anæmic patient with paroxysmal nocturnal hæmoglobinuria. The test animals were female mice of the MRC *TO* and Schneider strains and weighed 16–24 gm. Before the test, they were maintained for 14 days in a tank with air at a pressure of half an atmosphere, and an air flow through the tank sufficiently great to keep the carbon dioxide concentration below 1 per cent. Water and food (MRC cube diet 41) were supplied

[*] Beit Memorial Research Fellow.

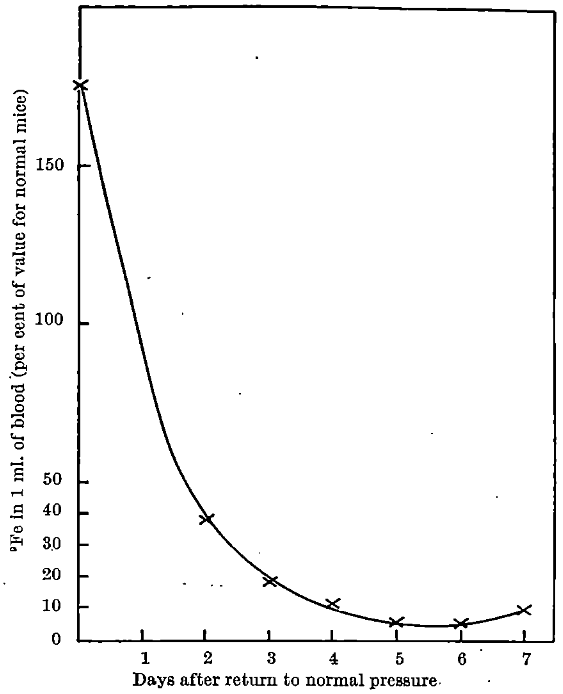

Fig. 1. Depression of red cell formation in mice returned to air at normal pressure after two weeks in air at half an atmosphere pressure
Appearance of a tracer dose of iron-59 in 1 ml. of blood of female *TO* mice (20 hr. after intravenous injection of $0\cdot1\mu$c. ^{59}Fe-citrate) at various time-intervals after return of the mice to normal pressure. Results expressed as percentage of iron-59 appearing in blood of normal mice

ad lib. and the tank was opened to the atmosphere for a short period each day for routine animal care. Hæmatocrits were estimated by a micro-method. Blood volume was measured using red cells labelled with chromium-51 which, before use, were screened by passage through a normal mouse to remove cells damaged during labelling. Red cell mass was derived from hæmatocrit and blood volume. The incorporation of iron-59 into red cells was measured 20 hr. after intravenous injection of a tracer dose of 0·1 μc. iron-59 citrate; a 20-hr. time-interval was selected for this measurement, as the appearance of iron-59 in red cells was then small and less than 1 per cent of the injected iron-59 remained in the plasma.

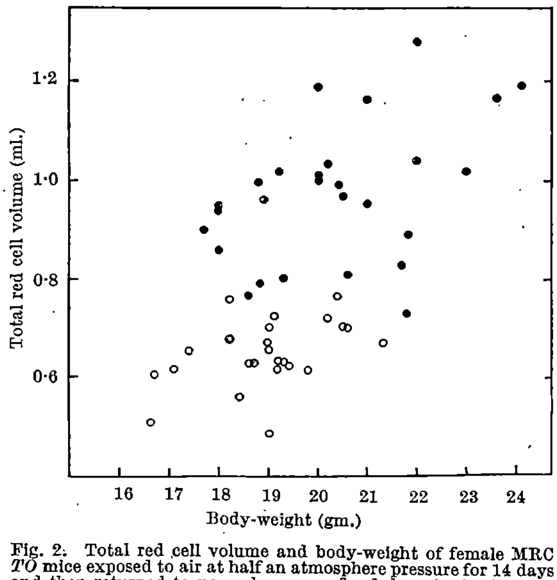

Fig. 2. Total red cell volume and body-weight of female MRC *TO* mice exposed to air at half an atmosphere pressure for 14 days and then returned to normal pressure for 6 days (series '14 + 6')
○, Normal; ●, '14 + 6'

Mice which had spent 14 days in air at half an atmosphere were studied at various times after they had been returned to normal pressure. Four or six days after the mice had been returned to normal pressure, the incorporation of iron-59 into red cells was depressed (Fig. 1), their red cell masses were increased (Fig. 2) and, in MRC *TO* mice at 4 days and 6 days, their hæmatocrits were above the normal range (Fig. 3). Blood volumes at (14 + 4) and (14 + 6) days were approximately 7·5 per cent of body-weight.

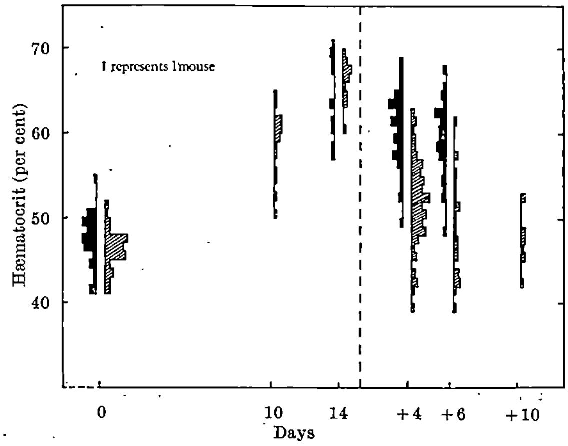

Fig. 3. Hæmatocrits of female MRC *TO* and Schneider mice exposed to air at half an atmosphere pressure for 14 days and then returned to normal pressure. Frequency distribution of hæmatocrits are shown as histograms
Black, *TO*; shaded, Schneider

On the basis of these results, the response to erythropoietin was investigated in mice which had spent 14 days in air at half an atmosphere pressure and which were killed 4 or 6 days after their return to normal pressure. These series are referred to as '14 + 4' and '14 + 6', respectively. The routine of the test is essentially similar to that used by other workers and is shown in Table 1. The response was taken as the percentage of the administered iron-59 present in the blood 20 hr. after intravenous injection of the iron-59; the blood volume was calculated as 7·5 per cent of body-weight. The log dose–response relationships obtained with small groups of mice treated with rabbit or sheep erythropoietin are shown in Fig. 4. From these graphs it may be seen that both the MRC *TO* and the Schneider mice are satisfactory test animals for the estimation of erythropoietin. *TO* mice, series 14 + 4, have been selected for our routine assay of erythropoietin. With rabbit erythropoietin, the log dose–response regression line did not differ significantly from linearity over a thirty-fold range of doses; its slope (b) was 16·03 and the index of precision (λ) was 0·35. Sheep erythropoietin tested in this system also gave a linear regression with slope 20·73 and index of precision (λ) 0·22. Over a longer range of doses, the log dose–response relationship was sigmoid in form. In this series the range of hæmatocrits of test animals was above the normal. Thus measurement of hæmatocrit was used to assess whether a test extract had

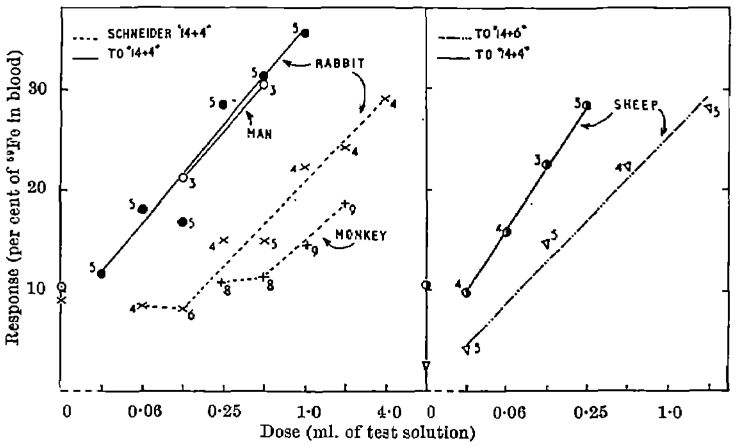

Fig. 4. Log dose–response regression lines obtained with MRC *TO* mice series '14 + 4' and '14 + 6' and with Schneider mice series '14 + 4' treated with preparations of erythropoietin from plasma of rabbit, sheep, monkey and man. Figures on the graph show numbers of animals used

caused hæmolysis, so that affected animals in which response might be increased by secretion of endogenous erythropoietin might be excluded from the test (cf. Winkert and Gordon[15]). In routine assays, results from mice with hæmatocrits below 50 per cent were discarded.

TO mice killed on day (14 + 6) may be advantageous for certain assays. These animals gave a base-line which was lower and more consistent than that obtained with the '14 + 4' series. They were sensitive to as little as 0·25 'cobalt units'[16] of erythropoietin and responded to this with a significant increase above the base-line incorporation of iron-59. The hæmatocrits of *TO* mice, series '14 + 6', overlapped little with the normal range and were also used to show whether treatment had caused hæmolysis. The Schneider mice, series '14 + 4', were not selected for routine assays because they were less sensitive to small doses of erythropoietin than the *TO* mice, and their range of hæmatocrits overlapped with the range for normal Schneider mice.

Data obtained with human erythropoietin administered to *TO* mice, series '14 + 4', and with monkey erythropoietin administered to Schneider mice, series '14 + 4' are also included in Fig. 4. These show that the system responds to erythropoietins prepared in various ways from four species, namely, rabbit, sheep, man and monkey; moreover, the slopes of the regression lines obtained with rabbit, sheep and human erythropoietin did not differ significantly ($P = 0{\cdot}35$).

Table 1. ROUTINE TEST PROCEDURE FOR USE OF MICE MADE POLYCYTHÆMIC BY EXPOSURE TO HYPOXIA

	Day of test	
	Series '14+4'	Series '14+6'
Mice maintained in air at half atmosphere pressure	0–14	0–14
Mice returned to normal pressure	14	14
First injection of test material (68 hr. before killing)	15	17
Second injection of test material (44 hr. before killing) (Each injection made up to 1 ml. with saline and given intraperitoneally)	16	18
^{59}Fe-citrate, 0·1 μc. in 0·2 ml. saline, injected intravenously (20 hr. before killing)	17	19
Weigh, bleed and kill mice (avertin anæsthetic)	18	20
Measure hæmatocrit and count ^{59}Fe present in sample of blood using a well-type scintillation counter		

This method has certain advantages over the methods in common use for estimation of erythropoietic activity. The labour and cost of transfusion, and the possibility of non-specific stimulation in a starved animal is avoided by the suppression of endogenous erythropoiesis with a polycythæmia of each animal's own red cells. Our test animal is a more physiological preparation than a starved or transfused animal. The mice are easily prepared in large numbers and the assay may thus be planned on a statistical basis. The system is at least as sensitive as other *in vivo* methods for the estimation of erythropoietin[17].

Garcia[6] has shown that a preparation of human urinary erythropoietin which stimulates incorporation of iron-59 into red cells in the starved rat, will also increase the total red cell mass in rats. Keighley *et al.*[18] have shown that one preparation of rabbit plasma erythropoietin induced an increase in the total red cell volume, hæmoglobin concentration and hæmatocrit of normal rats; it stimulated incorporation of iron-59 into red cells of normal, starved and hypophysectomized rats and caused a reticulocytosis in normal rats and polycythæmic-transfused mice. These test systems reflect various aspects of erythropoiesis. The incorporation of iron-59 into red cells measures chiefly hæmoglobin synthesis and only indirectly reflects division of erythropoietic cells. Reticulocytosis measures chiefly maturation of normoblasts, but it may be produced by release of reticulocytes. At the present time it is not known if these and other aspects of erythropoiesis are all controlled by one and the same 'erythropoietin' molecule. It is therefore essential that estimates of the relative erythropoietic activities of various preparations should be correlated by simultaneous studies using different assay systems.

TRYPTAMINE RECEPTORS IN THE CENTRAL NERVOUS SYSTEM

By Dr. J. R. VANE
Department of Pharmacology, Royal College of Surgeons, Queen Square, London, W.C.1

Dr. H. O. J. COLLIER and Dr. S. J. CORNE
Department of Pharmacological Research, Parke, Davis and Co., Hounslow, Middlesex

AND

Dr. E. MARLEY and Dr. P. B. BRADLEY
Department of Experimental Psychiatry, Medical School, University of Birmingham

THE actions and role of 5-hydroxytryptamine (5-HT) in the central nervous system are of great interest. Since injected 5-HT does not readily enter the central nervous system, Vane[1] suggested studying the central actions of related compounds such as α- or *N*-alkyl-tryptamines and their 5-methoxy derivatives, which are able to pass the blood-brain barrier and resist attack by monoamine oxidase (MAO). We describe here some effects of tryptamine, *dl*-α-methyltryptamine (MT), *dl*-α-ethyltryptamine (ET), *dl*-5-methoxy-α-methyltryptamine (MeOMT) and *N*,*N*-dimethyltryptamine (DMT) on the behaviour of animals and on their responses to other centrally acting drugs, on central electrical activity and on spinal reflexes. The 5-HT-like actions of these compounds on isolated smooth muscle have already been described[1,2].

Spontaneous Locomotion in Mice

Locomotion was measured as the number of breaks of an infra-red beam in modified Dews[3] activity boxes. Administered intraperitoneally to normal mice, MT, ET and, less strongly, MeOMT stimulated spontaneous locomotion, while DMT was inactive (Table 1). Tryptamine, 5-HT and iproniazid depressed locomotion, confirming the results of Brown[4]. Intravenously, however, tryptamine produced a brief episode of excitement followed by a prolonged period of depression.

Table 1. POTENCIES OF TRYPTAMINES AND OTHER COMPOUNDS IN MICE

Compound	Effective dose (mgm./kgm. i.p.) producing stimulation (*S*) or depression (*D*) of locomotion*	Effective dose (mgm./kgm. i.p.) producing reversal of reserpine ptosis‡
Tryptamine	50 (*D*)	190
α-Methyltryptamine	12·5 (*S*)	9·4
α-Ethyltryptamine	12·5 (*S*)	28·3
5-Methoxy-α-methyltryptamine	50 (*S*)	> 60 §
N,*N*-Dimethyltryptamine	No effect at 50	42·5
5-Hydroxytryptamine	50 (*D*)	> 300 ‖
Iproniazid	> 400 (*D*)†	No effect at 500
β-Phenylisopropylhydrazine	50 (*S*)	33
Amphetamine	2 (*S*)	5·8

* Locomotion was measured as the number of breaks of an infra-red beam in modified Dews (ref. 3) activity boxes. The effective dose is that which increased or decreased geometric mean activity count by a factor of 3 compared with that of control mice ($P < 0{\cdot}05$), when given within the dose-range 12·5, 25, 50, 100, 200 and 400 mgm./kgm. or in the case of amphetamine 1, 2 and 4 mgm./kgm.

† At this dose locomotion was depressed ($P < 0{\cdot}1$).

‡ Ptosis was induced by intraperitoneal injection of 4·0 mgm./kgm. reserpine 18 hr. before the test. The effective dose is that which in a group of 10 mice gives a score for reversal of ptosis of 10 out of a possible maximum of 20 on the scale 0 = full ptosis; 2 = eyes fully open; 1 = any intermediate state between 0 and 2.

§ At this dose a maximum score of 8/20 was obtained.

‖ At this dose a maximum score of 9/20 was obtained.

In another series of experiments, mice were given a larger dose of β-phenylisopropylhydrazine (PIH) than that necessary to inhibit brain MAO completely[5,6]. 18 hr. later, we treated them with MT, ET or iproniazid. Table 2 shows that MT and ET powerfully stimulated locomotion in normal mice and in mice after inhibition of brain MAO.

Table 2. EFFECTS OF α-METHYLTRYPTAMINE (MT), α-ETHYLTRYPTAMINE (ET) AND IPRONIAZID ON LOCOMOTORY ACTIVITIES OF NORMAL MICE AND MICE TREATED WITH MAO INHIBITOR (β-PHENYLISOPROPYLHYDRAZINE (PIH) 40 MGM./KGM. INTRAPERITONEALLY 18 HR. PREVIOUSLY)

Exp. No.	Treatment dose/kgm. i.p.	Mean activity count* and significance of difference	
		Without PIH	After PIH
1	Saline, 10 ml. MT, 20 mgm.	279 1,652 } $P < 0{\cdot}001$	236 2,771 } $P < 0{\cdot}001$
2	Saline, 10 ml. ET, 20 mgm.	102 1,355 } $P < 0{\cdot}001$	169 3,751 } $P < 0{\cdot}001$
3	Saline, 10 ml. Iproniazid, 100 mgm.	108 100 } $P > 0{\cdot}75$	236 145 } $P > 0{\cdot}10$

* Each value is the geometric mean of counts obtained over 4 hr. from 6 activity boxes, each containing 3 mice.

Anti-Reserpine Activity in Mice

Anti-reserpine activity was measured by the extent of reversal of ptosis produced by injecting reserpine 4·0 mgm./kgm. intraperitoneally 18 hr. previously. Table 1 shows that the tryptamines were active in this test, MT being the most and 5-HT the least potent. Amphetamine and PIH were also potent; but iproniazid ineffective. However, when given some hours before reserpine, iproniazid prevents ptosis[7].

Experiments on Unrestrained Conscious Cats

Intravenous tryptamine caused convulsions, tonic extension of the limbs, unsheathing of claws, hissing and snarling, piloerection, salivation, mydriasis and retraction of the eyelids: all these effects have already been described by Laidlaw[8]. The animals behaved as though angry or afraid. These reactions lasted for about 5 min., after which the animals were subdued for some hours. However, if MAO had been inhibited by injection of PIH (10 mgm./kgm. intraperitoneally 18 hr. beforehand), the phase of excitement following tryptamine lasted several hours. In untreated cats, MT or ET (5 mgm./kgm. intravenously) produced excitement lasting 4–5 hr.

Intraperitoneally, MT, ET or DMT (0·5–2·0 mgm./kgm.) caused recurrent extensor and flexor spasms of the limbs, ataxia, apparent reluctance to move and bewilderment. These effects, which lasted for more than 6 hr., were reduced or abolished within 2 hr. by intraperitoneal injection of 2 mgm. bromlysergic acid (BOL).

In cats with implanted cortical electrodes, MT, ET, MeOMT or DMT (2 mgm./kgm. intraperitoneally) did not produce electrocortical alerting. Within 15 min., however, bursts of 6–10 c./sec. high-voltage (250–400 μV.) electrocortical activity appeared and these were maintained unchanged for more than 6 hr.

Cat Encéphale Isolé Preparations

MT (0·5–2·0 mgm./kgm. intravenously) produced immediate and prolonged behavioural arousal. There was also very brief electrocortical alerting, which was replaced in 30 min. by bursts of high-voltage electrical activity, similar to that described above in conscious cats, or by high-voltage 2–4 c./sec. activity. These changes were found in all the cortical areas except the hippocampus. MT modified the normal reciprocal relationship which exists between electrocortical activity in the hippocampus and in other areas. The bursts at 2–4 or 6–10 c./sec. seen in the cortex could also be recorded from deep structures, such as the thalamic nuclei and the reticular formation in the brain stem. Subsequent intravenous injection of 2 mgm. BOL abolished or reduced the electrical patterns attributable to MT gradually over 1–2 hr.

In addition to changing spontaneous electrical activity, MT also affected evoked potentials. Thus the threshold for electrocortical arousal on stimulating the brain-stem reticular formation was raised from 0·4 to 1·2 V. and that on stimulation of the thalamic nuclei from 2·5 to 4·0 V. Similarly, the thresholds for eliciting recruiting and augmenting responses by low-frequency stimulation of the appropriate thalamic nuclei were raised as were the thresholds for arousal with tactile and auditory stimuli.

Spinal Reflexes

These were studied in spinal or chloralosed cats. In a polysynaptic reflex (twitch of the tibialis anterior muscle evoked by stimulation of the central end of the cut posterior tibial nerve), increase of both basal tension and peak twitch tensions with fused or partially fused tetani followed intravenous injection of tryptamine, MT, ET, DMT or MeOMT (0·5 mgm./kgm.). The facilitating effect of tryptamine was brief and larger doses abolished the response. However, with tryptamine after MAO inhibition or with MT alone, a tetanic response was followed by protracted augmentation of the twitch and a single sensory nerve stimulus produced repetitive muscle contractions. These compounds similarly facilitated a monosynaptic reflex (knee jerk).

Several observations showed that the facilitating effects of the tryptamines originated in the spinal cord: (1) these substances increased the spike potential recorded from the ventral root after stimulation of the corresponding dorsal root; (2) they were more potent when injected into a spinal artery; (3) they did not enhance responses of muscle to direct stimulation of the motor nerve or of the muscle itself; and (4) pressor effects of comparable size to those produced by tryptamines, but elicited by tyramine, adrenaline or noradrenaline, did not increase the reflexes.

Reduction of the spike potential after the initial increase sometimes followed injection of tryptamine. 5-HT (1 mgm./kgm. intravenously) enhanced both reflexes, but after a much longer latency, possibly because 5-HT does not easily cross cell barriers[1]. BOL (2 mgm. intravenously) and another specific antagonist of 5-HT—1-methyl-D-lysergic acid butanolamide[9] (UML-491)—at the same dose, reduced or abolished these reflexes, and also the facilitatory actions of the tryptamines.

Depression of both reflexes by acute or chronic reserpine or acute chlorpromazine treatment was reversed by intravenous injection of any of the compounds, MeOMT being the most potent.

Conclusions

In all the effects we have studied, tryptamine differed from MT and ET only in depressing spontaneous locomotion in mice, although for a brief initial period it caused excitement. Greig *et al.*[10,11] have claimed that MT and ET owe their central stimulatory action to inhibition of MAO, causing an accumulation of catechol amines or HT in the brain. However, two reasons show that MT and ET do not only or even mainly act in this way: (1) their stimulatory effect on locomotion was undiminished by prior inhibition of MAO (Table 2); and (2) they take effect rapidly. Another explanation of the action of substituted tryptamines has been advanced[12]—that they increase the availability of free HT by preventing its storage. However, this explanation seems unlikely to be important, since the substituted tryptamines act after reserpine, which has already inhibited storage of HT. These considerations suggest that the substituted tryptamines act directly on receptors in the central nervous system. Gaddum[13] has argued that tryptamine and 5-HT share common receptors in the gut, and Tedeschi, Tedeschi and Fellows[14] have advanced a similar hypothesis for the central nervous system. That substituted tryptamines as well as tryptamine and HT are antagonized by BOL and UML-491 suggests that they all act on the same receptors—the tryptamine receptors. That electrical responses to substituted tryptamines can be recorded from cortex, thalamus, brain stem and spinal cord suggests that tryptamine receptors are widely scattered throughout the central nervous system. In spinal reflexes in particular, the high potency of tryptamines and their antagonism by specific antagonists of 5-HT suggest that tryptamines naturally present may have a physiological function.

The substituted tryptamines were prepared in the Department of Chemical Research, Parke, Davis and Co., Hounslow. We wish to thank Dr. R. E. Bowman for helpful discussions, Dr. B. T. Warner for statistical advice and Mr. R. W. Pickering for experimental assistance. We also wish to thank Ciba Laboratories, Ltd., for supplies of reserpine and Sandoz Products, Ltd., for UML-491.

INHERITANCE OF SUSCEPTIBILITY TO INDUCED PULMONARY TUMOURS IN MICE

By DR. D. S. FALCONER* and JOYCE L. BLOOM

Institute of Animal Genetics, Edinburgh

THE inheritance of cancer susceptibility is not amenable to study by the methods of Mendelian genetics, because many genes are involved which cannot be recognized individually, and any measure of the degree of susceptibility is subject also to non-genetic variation[1]. The methods of quantitative genetics must, therefore, be applied, and this article describes briefly the results of an investigation by these methods. Pulmonary tumours induced by urethane were chosen for study, because the manifestation of this form of cancer can be measured quantitatively, by the number of tumours present. All mice were given the same treatment: 0·1 ml. of 10 per cent urethane in distilled water injected intraperitoneally at 3 weeks of age, followed by a second injection of 0·28 ml. at 9 weeks. The mice were dissected at 23 weeks of age and the tumour nodules visible to the unaided eye on the surface of the lungs were counted. The number of tumours counted were transformed to square roots for the purpose of computation.

The object of the work was to determine the relative importance of heredity and environment as causes of the differences of tumour number between the individuals of a genetically heterogeneous, or random-bred, strain. The observed variance, that is, the phenotypic variance (V_P) among the individuals of a genetically heterogeneous strain is the sum of two principal components, the genetic variance (V_G) and the non-genetic, generally termed the environmental, variance (V_E); so that:

$$V_P = V_G + V_E$$

Then the ratio of the genetic to the total variance, V_G/V_P, measures the relative importance of genetic differences between individuals in determining the differences of tumour number between them. This partitioning of the variance can be made if a group of genetically homogeneous individuals is available, such as the F_1 of a cross between highly inbred lines. The variation among these, which contains no genetic component, provides a measure of the non-genetic variation; and, if this can be assumed to represent the non-genetic variation in the non-inbred strain, an estimate of the genetic variance can be obtained by subtraction. The genetic variance can be subdivided into an additive component (V_A), which is the variation chiefly responsible for the resemblance between relatives, and the remainder, or non-additive component (V_{NA}), which arises from dominance and other genetic complexities. The additive genetic variance can be estimated from the resemblance between relatives in a genetically heterogeneous strain. Thus the measurement of the variances of a genetically heterogeneous strain and of a genetically uniform group, together with the measurement of the resemblance between relatives in the heterogeneous strain, leads to a partitioning of the phenotypic variance of the heterogeneous strain as follows (for a more complete explanation, see ref. 2):

$$\underset{\text{(phenotypic)}}{V_P} \quad = \quad \underbrace{V_A + V_{NA}}_{\text{(genetic)}} \quad + \quad \underset{\text{(non-genetic)}}{V_E}$$

The ratio of the additive genetic variance to the total (V_A/V_P), known as the heritability, measures the extent to which differences of tumour number are transmitted from parents to offspring. Only in the absence of genetic complexities giving rise to non-additive variance does it measure the degree of genetic determination, or the relative importance of genetic differences in determining the phenotypic differences between individuals.

The genetically heterogeneous strain used in this work, known in the laboratory as *JC*, originated from crosses between several non-inbred strains and had been maintained for some thirty generations by random mating. The genetically uniform mice, from which the non-genetic variance was estimated, consisted of thirty F_1's made from six highly inbred strains crossed in all combinations, and the inbreds themselves. The variances of the inbreds did not differ from those of the F_1's, so there was no reason to exclude them. Counts were made on 723 F_1 and inbred individuals. The mean tumour number ranged from 0·9 to 25·4, with an overall mean of 11·7. (In what follows the F_1's and inbreds together will be referred to as the uniform groups.)

The results are shown in Table 1. The transformation to square roots did not fully succeed in rendering the variance independent of the mean, and the variance in the uniform groups tended to be higher in those with higher means. Since most of the groups had higher means than the heterogeneous strain, it was therefore necessary to adjust the estimate of the uniform group variance to allow for this difference. This was done from the regression of the standard deviation on the mean, which led to an estimate of the expected variance of uniform groups having the same mean tumour number as the heterogeneous strain. The unadjusted estimate of the mean variance in the uniform groups was 0·527, and the adjusted estimate was 0·325. The comparison of the variances of the heterogeneous strain and the uniform groups adjusted in this way leads to the conclusion that 58 per cent of the variation in tumour number in the heterogeneous strain

Table 1

Total phenotypic variance of random bred strains (V_P)	0·771 ± 0·042
Phenotypic variance of uniform groups (adjusted) (V_E)	0·325
Total genetic variance of random-bred strain ($V_G = V_P - V_E$)	0·445
Degree of genetic determination (V_G/V_P) = 0·445/0·771 =	58 per cent
Regression of offspring on mid-parent	0·323 ± 0·051
Correlation of full sibs	0·218 ± 0·044

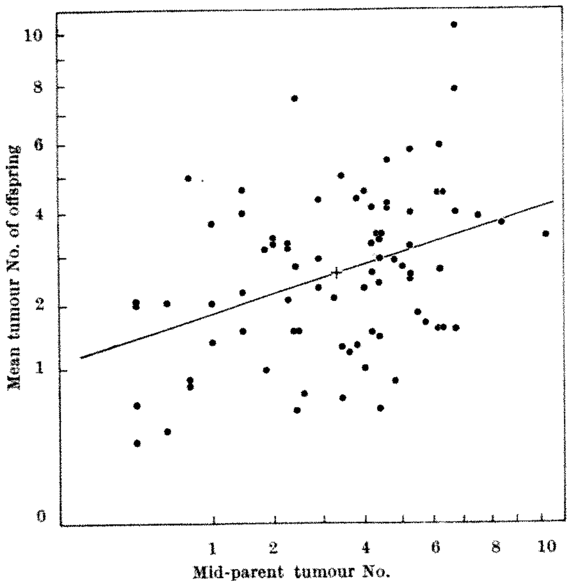

Fig. 1

was genetic in origin. This measures the relative importance of heredity as a cause of differences in tumour number.

The additive genetic variance in the heterogeneous strain was estimated from the regression of offspring on the mean of their two parents. Counts were made on 518 offspring in 79 families. The mean tumour number was 3·4. The correlation of full sibs (litter-mates) was also estimated. As a measure of the additive genetic variance this is liable to upward bias from non-additive genetic variance and from environmental causes of variation common to litter-mates, such as might arise from maternal effects or from the experimental procedure. The scatter diagram shown in Fig. 1 illustrates the resemblance between offspring and parents. Each point represents the mean tumour number among the offspring of one pair of parents plotted against the mean tumour number of the parents. The straight line is the computed regression of offspring on mid-parent (that is to say, the mean of the two parents), and the slope of this line measures the degree of resemblance between offspring and parents, which estimates the heritability (V_A/V_P). This was 32 ± 5·1 per cent. Thus, the heritability differs materially from the ratio V_G/V_P, which was 58 per cent. This indicates the presence of non-additive genetic variance arising from dominance and other genetic complexities in the action of the genes controlling tumour number. If there were no non-additive genetic variance and no maternal effects the full-sib correlation would estimate half the heritability. Doubling the observed correlation yields an estimate of 44 ± 9·2 per cent. This is in excess of the estimate from the offspring–parent regression, which is to be expected when non-additive variance is present.

These analyses show that about 58 per cent of the variation in tumour number between the mice of the strain studied was caused by genetic differences. The remaining 42 per cent, which is non-genetic in origin, can be subdivided by consideration of the fact that the number of tumours counted does not necessarily indicate precisely the true susceptibility of the individual. A number of individuals of exactly the same susceptibility would be expected to vary in the number of tumours present, because the occurrence of a tumour can be regarded as a chance event with a certain probability characteristic of the susceptibility of the individual. The variance of tumour number will, therefore, have a component of variance attributable to chance in addition to the variance arising from individual differences of susceptibility. There is evidence[3] that the chance variation follows a Poisson distribution; the variance attributable to chance will then be equal to the mean tumour number[4], when the mean and variance are computed from the untransformed counts. The mean of the (untransformed) tumour numbers in the random-bred strain was 3·4 and the variance was 8·5. The variance attributable to chance (that is, 3·4) therefore represents 40 per cent of the total variance of tumour number. This leaves only 2 per cent of the variance of tumour number to be attributed to non-genetic differences of susceptibility together with differences due to experimental error, such as might have arisen from variation in the dosage of urethane administered to different individuals. It is not altogether credible that non-genetic differences of susceptibility, together with experimental error, account for as little as 2 per cent of the variation. The chief source of possible error in this estimate lies in the adjustment of the variances of the uniform groups, and it is not a simple matter to attach a standard error to the adjusted estimate. A second source of possible error lies in the amount of variance to be attributed to chance. Until these sources of error have been excluded, or confirmatory evidence obtained from other experiments, only a qualitative conclusion can be accepted, namely, that environmental sources of variation are relatively unimportant, and an individual's genetic constitution is the major determinant of its true susceptibility to urethane as a carcinogenic agent.

The results of this work are summarized in Table 2, which shows the relative importance of heredity, environment and chance as causes of the differences between individuals in the number of tumours developed. The figures are subject to some possible error, but the following conclusions can be drawn. More than half the variation of tumour number among the mice of the strain investigated results from genetic differences between the individuals; but, as a result of genetic complexities, only about one-third of the variation is 'inherited' in the sense of being transmitted from parents to offspring. A major part of the non-genetic variation of tumour number is attributable to chance, and environmental differences between individual mice are relatively unimportant as determinants of an individual's susceptibility to the carcinogenic action of urethane.

Table 2

	Total (per cent)
Genetic variance of susceptibility	
Additive	32
Non-additive	26
Total	58
Non-genetic variance of susceptibility	2
Chance variance of tumour number	40
Total variance of tumour number	100

A MORPHOGENETIC EFFECT OF BETA-MERCAPTOETHANOL

Distribution of Water in the Embryo

CELLULAR mechanisms responsible for the uptake and distribution of water in the embryo play an important part in normal development[1]. Prof. Brachet's reports[2] on the effects of β-mercaptoethanol on the normal development of urodele embryos, which he attributed to its effect on the fibrous proteins responsible for morphogenetic movements, were therefore of particular interest, because two of the abnormalities he described—the collapse of the blastocœl and the failure of the neural tube to close—clearly resulted in an abnormal distribution of water in the embryo.

This prompted me to carry out a series of quantitative experiments to measure the effect of this reagent on the uptake and distribution of water during the formation of the blastula and gastrual of *Xenopus leavis* (Daud.). The results were surprising, for they showed that under the conditions of my experiments, $M/500$ mercaptoethanol had little or no effect on the morphogenetic movements themselves, but it did have a pronounced effect on the uptake and, particularly, the distribution of water in the embryo.

Having first established that the reagent had no effect on the reduced weight of the embryos by weighing single embryos on a Cartesian diver balance before and after treatment for 3 hr. with $M/100$ mercaptoethanol, it was assumed that the density of the embryos could change only by taking up or losing water. (It had previously been established that the reduced weight of normal embryos remained constant until the early tail-bud stage.) Thus, it was possible to follow the effect of the reagent on the water content of the embryo by measuring the density of treated and control embryos in a density gradient of colloidal thorium oxide in water[3]: and its effect on the volume of the cells themselves could be determined by repeating the process on open embryos from which the contents of the intercellular spaces had been removed. The results of one such experiment are shown in Table 1, and the corresponding volume changes, calculated from the mean densities and the mean reduced weight of the experimental embryos, are shown in the histogram (Fig. 1).

Table 1

Control embryos in buffered tap water pH 7·4 at 20° C. Treated embryos in buffered tap water pH 7·4 at 20° C. + $M/500$ β-mercaptoethanol

	Duration of treatment Age (hr.) In	Out	No. of embryos	Mean density (20° C.) at end of treatment Intact gm./ml.	Open gm./ml.
Control	—	—	5	1·0770	1·0887
Treated	2	10	5	1·0780	1·0887
Control	—	—	6	1·0620	1·0840
Treated	2	22	5	1·0732	1·0812

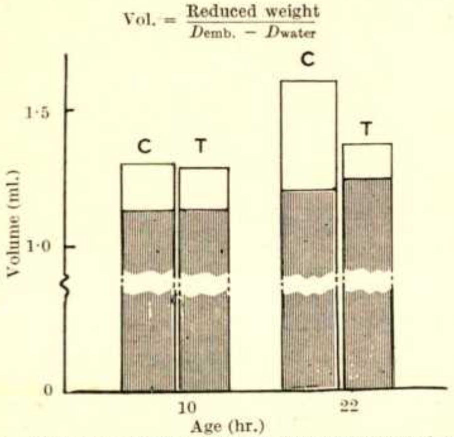

Fig. 1. Histogram showing effect of β-mercaptoethanol on the volume of *Xenopus* embryos. Shaded areas, vol. of cells; unshaded, vol. of intercellular cavities

It will be seen that at 10 hr. there is very little difference between control embryos and embryos laid at the same time which had been in a solution of $M/500$ mercaptoethanol from the four-cell stage onwards. The volume of the cells in both cases is the same. At 22 hr., however, there is a marked difference. The density of the treated embryos is very much greater than that of the controls, whereas the density of their cells is slightly less. This means that the volume of the intercellular cavities of the treated embryos is very much less than that of the controls (Fig. 1). The treated embryos differ from the controls in one other important respect—they lie upside down in the vitelline membrane, due to the presence of a liquid-filled cavity on their ventral surface. The presence of this cavity became more pronounced if treated embryos were removed from the reagent at this stage and transferred to tap water (Fig. 2).

Serial sections and time-lapse films clearly showed that this cavity was the cavity of the blastocœl which, having formed normally, failed to empty during gastrulation. The morphogenetic movements involved in the formation of the archenteron and its associated structures did not appear to be affected by the treatment, and all the structures normally found in transverse sections of normal embryos could be identified. The only obvious abnormality was that the archenteron cavity was empty. At a later stage the treated embryos also differed from the controls, as Brachet reported, in having open neural tubes. It should be mentioned in passing that nuclear counts from macerated embryos showed that treated and control embryos have the same number of nuclei.

It seems reasonable to conclude, therefore, that the primary effect of the mercaptoethanol is not, as Brachet has suggested, on the mechanisms responsible for the morphogenetic movements themselves, but on the mechanisms responsible for controlling the

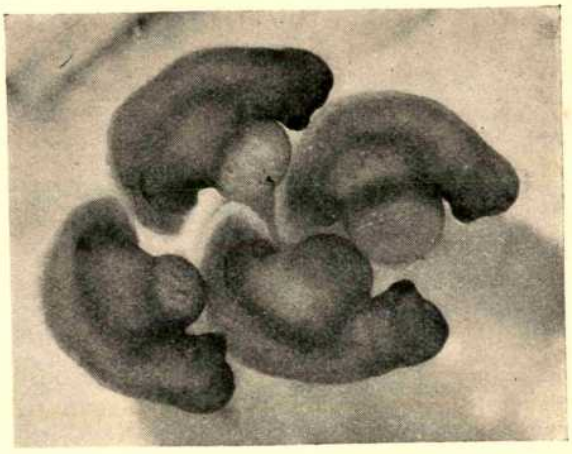

Fig. 2. *Xenopus* embryos showing persistent blastocœl cavities after 15 hr. in tap water following treatment for 20 hr. with $M/500$ mercaptoethanol at 20° C.

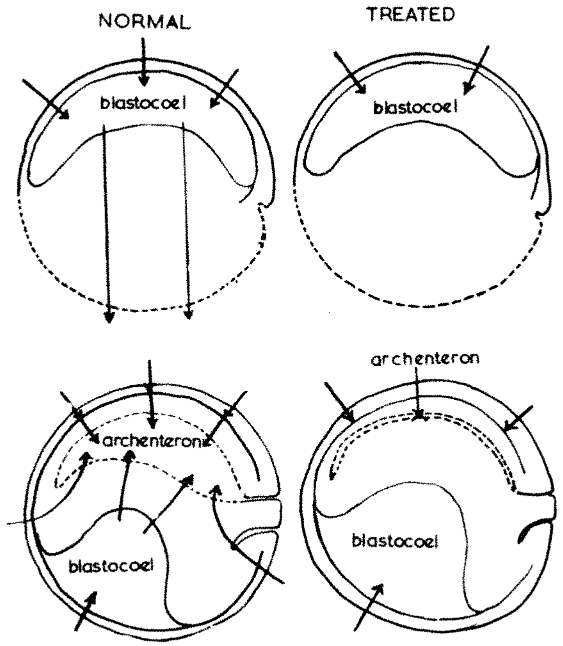

Fig. 3. Diagram to illustrate the effect of the net water fluxes in normal and treated *Xenopus* embryos

distribution of water in the embryo. This in turn may be the result of its effect on the bonding of specific proteins, for as I have shown[1], the distribution of water in the embryo is probably due to the difference in polarity of cellular mechanisms located in the cell membranes, and not to simple osmotic and hydrostatic gradients.

Thus, in the normal embryo, these mechanisms are thought to be polarized in such a way that there is a net influx of water through the cells of the animal pole and a net efflux through the vegetative pole cells, the difference between the two fluxes being responsible for the accumulation of water in the blastocœl, and after invagination for the transfer of water into the archenteron. The failure of treated embryos to transfer water from the blastocœl into the archenteron may therefore be explained by supposing that the reagent reduces the endodermal efflux to zero, leaving a small ectodermal influx to account for the formation of the blastocœl which, as the experiments show, is unaffected (Fig. 3).

This work is being reported in more detail elsewhere[4].

Distribution of Water in the Chick Blastoderm

It has been shown experimentally that the effect of β-mercaptoethanol on the morphogenesis of the anuran *Xenopus leavis* is largely due to an abnormal uptake and distribution of water in the treated embryos. This was explained by suggesting that the reagent affects the mechanisms responsible for controlling the water content of the embryonic cells in such a way that the normal net efflux of water through the endoderm cells is abolished, so preventing the transfer of water into the archenteron, leaving a small residual ectodermal influx to account for the formation of the blastocœl, which is unaffected[1].

The complexity of the geometrical relations between ectoderm and endoderm in the amphibian embryo makes it difficult to test this hypothesis. In the early chick embryo, on the other hand, the problem is greatly simplified because the ectoderm and endoderm are merely parallel sheets of cells. Moreover, their polarity has been demonstrated experimentally by New, who has shown that water is transferred through the chick blastoderm from the ectodermal to the endodermal surface[2]. Thus not only is the polarity the same as that postulated for the *Xenopus* embryo, but there must also be a similar difference in the magnitude of the fluxes to account for the small accumulation of liquid between the layers which occurs during the development of the normal blastoderm.

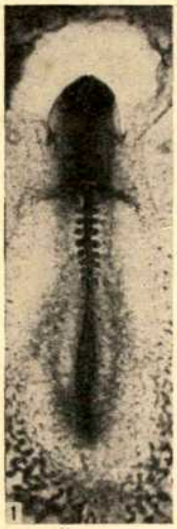
Accordingly, one of us (A. J.) has carried out a series of experiments to test the effect of β-mercaptoethanol on early chick embryos.

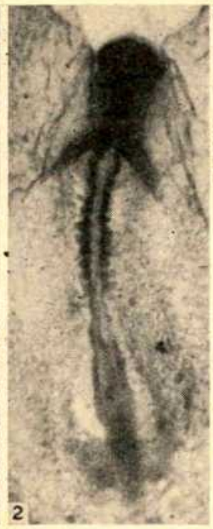
Chick embryos were explanted from eggs at the definitive streak stage (Hamburger and Hamilton stage 4)[3] and cultured *in vitro* using the technique described by New[5]. The β-mercaptoethanol was diluted with liquid egg albumen containing 10 per cent sterile saline solution (0·9 per cent) to give a final concentration of 4 or 5 m*M*, and 0·5 ml. of this solution was spread around the plastic ring on which the embryos were cultivated; in control experiments a solution of liquid egg albumen containing 10 per cent saline was applied in the same way. After treatment, the embryos were incubated for another 20–24 hr., that is, until the controls had reached stages 10–12 (Fig. 1). Some embryos were also treated *in ovo* at stage 4 by injecting 0·25 ml. of 400 m*M* solution of the reagent. These embryos were then allowed to develop for another 20–24 hr. before being explanted.

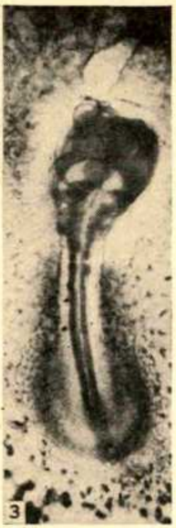
Macroscopic examination of treated embryos showed abnormal swelling of the blastoderm on either side of the mid-line and enlargement of the proamnion and the head. The neural tube in all cases failed to close, often along its entire length (Figs. 2 and 3).

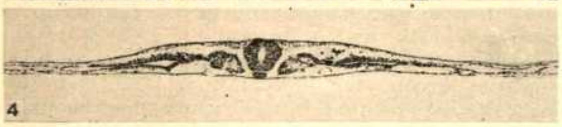
In transverse sections it was seen that the swelling of the blastoderm was the result of abnormally large spaces between the ectoderm and mesoderm, and between mesoderm and endoderm. This was especially noticeable in the region of the posterior somites and farther towards the caudal end of the embryo (Figs. 4 and 5). The extra-embryonic cœlom was also widened along the whole length of the embryos. In the cephalic region, the mesenchyme spaces were enlarged, and the mesenchyme cells were dispersed more than in the normal embryo. The increase in size of the head in treated embryos was in part the result of a considerable dilation of the main blood vessels (ventral and dorsal aortic roots) accompanied by a dilation of the heart ventricle.

The neural plate of treated embryos, especially where it failed to close along its entire length, sometimes showed necrotic changes in the median part of the neural groove, or scattered over the whole tissue. The notochord was sometimes poorly formed and not clearly detached from the surrounding mesenchyme cells, and finally, in some embryos, well-defined blisters were found in both the ectoderm and endoderm.









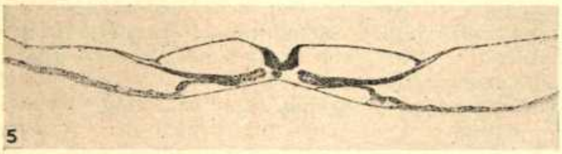


Fig. 1. Control chick embryo at stage 10 (× 15)
Fig. 2. Chick embryo after treatment with $M/250$ solution of β-mercaptoethanol. Note the open neural tube and widened omphalomesenteric veins (× 15)
Fig. 3. Chick embryos treated with $M/200$ solution of β-mercaptoethanol. Note the enlarged head, and open neural tube (× 20)
Fig. 4. Transverse section through a control embryo (stage 10) at the level of the last somite (× 40)
Fig. 5. Transverse section through an experimental embryo at the same level after treatment with $M/200$ β-mercaptoethanol (× 40)

These results show that in the chick, as in *Xenopus*, β-mercaptoethanol causes an abnormal distribution of water in the embryo: a distribution, which is in accord with the hypothesis outlined earlier. Thus if mercaptoethanol reduces the endodermal efflux in the chick as it does in *Xenopus*, the residual ectodermal influx would account for the abnormal accumulation of water between the two layers that has been observed.

The effect of the reagent on the volume of the cœlom is less easily explained. However, the fact that the myocœl when it forms is not abnormally large, although the extra embryonic cœlom is always greatly distended, suggests that the mesodermal cells are normally polarized centripetally with respect to the net transfer of water; but because the lateral plate mesoderm is so closely associated with the ectoderm and endoderm, the layers of cells which result—the somatopleur and splanchnopleur—have the same polarity as the ectoderm and endoderm respectively and are affected in the same way.

A further interesting feature of these experiments is the appearance of the neural plate in transverse sections of treated embryos; this suggests that its failure to close may simply be a mechanical consequence of the increased tension in the ectoderm caused by the abnormal accumulation of water. Attempts to test this hypothesis by puncturing the ectoderm of embryos that had been treated *in ovo* (see earlier) were inconclusive. The neural plate did not close up immediately the tension in the ectoderm had been relieved, although there was a limited closure after 2 hr. The embryos in these experiments were of course relatively old, and it is possible that permanent damage had occurred in the neural tissues. Moreover, the reagent may affect the differential water uptake of the cells on the upper and lower surfaces of the neural plate itself; a differential which must exist in the normal embryo to account for the changes in cell volume which occur during invagination.

In view of these results, it is suggested that the effects of other specific morphogenetic inhibitors, particularly those which tend to alter the S—S S—H equilibrium of the cells, may be the result at least in part of their effect on the distribution of water in the embryo and the mechanisms by which it is controlled.

A detailed account of this work will be published elsewhere.

IONIC CURRENTS IN MEMBRANE OF ACTIVE MUSCLE FIBRE

By DR. H. JENERICK

Department of Physiology, Emory University, Atlanta 22, Georgia

A NERVE or muscle fibre immersed in a large volume of fluid and carrying a propagated action potential at velocity s, will obey the following relationship, usually termed the cable equation:

$$(a/2Rs^2)\mathrm{d}^2V/\mathrm{d}t^2 = C\ \mathrm{d}V/\mathrm{d}t + I_i \qquad (1)$$

where a is the radius of the fibre, R is the resistivity of the cytoplasm, V is the membrane voltage, t is time, C is the membrane capacitance, and I_i is the membrane ionic current density. As a rule, this equation cannot be integrated since I_i is an unknown function of voltage and time. However, if the first and second time-derivatives of the action potential can be determined as functions of time, appropriate substitution into (1) will lead to a numerical solution for the membrane ionic currents associated with the action potential.

During investigation in this laboratory of the action potential of frog sartorius fibre, it was realized that much of the needed information lies in a record of the action potential in phase-plane co-ordinates, as in Fig. 1. Trans-membrane voltage (V) was recorded on the horizontal axis of the oscilloscope, while dV/dt (obtained electronically) was recorded simultaneously on the vertical axis. The entire spike-potential record develops clockwise from the initial spot at the left (resting potential − 92 mV.). The farthest horizontal excursion to the right is the peak of the spike (28 mV. overshoot). The large spot at the centre recorded the outside potential (zero) when the electrode was dislodged by the twitch. (The small peaked curve in the centre is the transient of the electrode pull-out; neither it nor the high-frequency hash on the entire record is significant.) The various regions of the phase plane record chosen for the analysis described in the text are labelled, and the arrows indicate the approximate boundaries of each region. This particular record was rotated slightly clockwise by a 3° phase-shift introduced by the differentiating network, and the inflexion point of the leading edge (at the top of the record) seems to occur at smaller membrane potentials than might be expected. It was possible, after analytical functions were fitted to various portions of the record, to obtain a description of the action potential in terms of several differential equations; that is, a set of functions where $dV/dt = f(V)$. These were integrated mathematically for $V = f(t)$, which in turn were differentiated successively for dV/dt and d^2V/dt^2 as $f(t)$, the functions required for the solution of the cable equation. It was necessary to separate the record by trial and error into several regions as indicated in Fig. 1, and to fit individual functions to each section, since no single function has been found which describes the entire course of the action potential. (Regions a and d are linear, b is closely fitted by a parabolic expression, and c by a modified cubic.) Once these functions were obtained from each record, they were integrated and differentiated as described, and yielded a set of functions suitable for direct substitution into the cable equation. Taking t as the independent variable, V and I_i were calculated point by point every 10–50 μsec. throughout the spike potential. The calculations for one record take about 2 days to complete, and this article summarizes results obtained in separate experiments from six typical fibres.

The list of fitted functions and derived equations describing the muscle spike-potential is lengthy (eighteen in all) and will not be presented here. However, the equation for region a is of particular importance and will be discussed briefly. As the action potential shown in Fig. 1 invaded the recording site, the advancing foot which develops exponentially in time[1] was necessarily transformed in the phase plane into a straight line of slope k_1 (ref. 2). It is suggested in refs. 1 and 2 that k_1 is equal to $(2RCs^2/a)$. The cell constants are thus obtained directly from this one portion of the phase plane record and permits a revision of (1) to:

$$I_i/C = (d^2V/dt^2)/(k_1) - dV/dt \qquad (2)$$

After selecting a value of 6μF./cm.² for the membrane capacitance from the average of published data, all calculated derivatives were corrected to give the membrane ionic current density I_i in m.amp./cm.², as illustrated in Fig. 2; also a portion of the spike-potential reconstructed in its usual form from the differential equations is shown. Fig. 2 represents a reconstruction of the spike potential and membrane ionic current obtained from the phase-plane record of Fig. 1. (Time in msec. Inward current in m.amp./cm.² is plotted as positive.) Calculations were carried to within a few mV. of the beginning of the decay of the after-potential. Since the time-constant of the after-potential is close to or equal to that of resting membrane, it would appear that the conductances of the active membrane have subsided, and the remainder of the action potential is not relevant to the present work. It should be emphasized that, as a result of setting appropriate boundary conditions for the equations describing each region of the phase plane record, the derivatives and hence the potential and the ionic current are continuous in time across each junction point and throughout the entire portion of the reconstructed spike-potential.

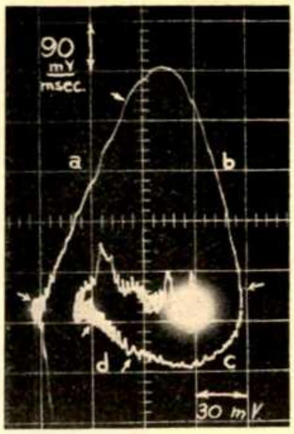

Fig. 1. Propagated action potential of a single surface fibre of the frog sartorius muscle recorded by a penetrating micro-electrode and displayed in the phase-plane
Conditions: 24° C., sodium chloride 110 mM, potassium chloride 2·5 mM, calcium chloride 4 mM, and phosphate buffer 1 mM at pH 7·3

The largest ionic current appears to be associated with the upstroke of the muscle fibre spike-potential,

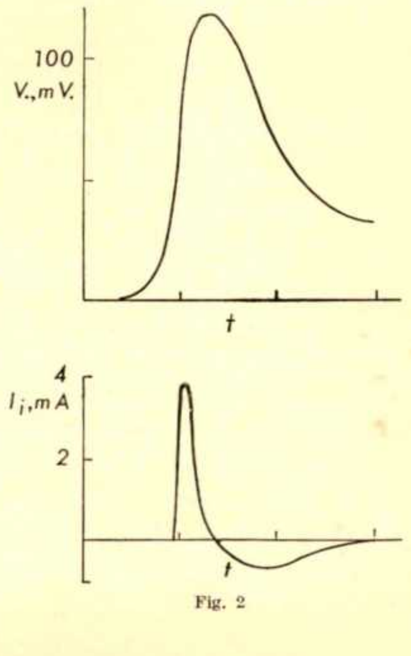

Fig. 2

as in the squid giant axon, and lasts somewhat less than 0·5 msec. at room temperature. Graphical integration of Fig. 2 predicts a net entry of positive charge during initial portions of the spike of about 7×10^{-12} mole/cm.[2] followed by a net exit of about 6×10^{-12} mole/cm.[2] during the terminal phase. These charges should balance, and the discrepancy is attributed to the difficulty involved in fitting a cubic equation to region *c* which is largely generated by the outward currents. Region *b* can be fitted more accurately and more confidence is placed in the corresponding portion of the inward current plotted against membrane voltage in Fig. 3. The solid curves plot the relation between the inwardly directed membrane ionic current/cm.[2] and the membrane voltage during the upstroke of two spike-potentials obtained from the same muscle under different conditions. The largest current was obtained when the muscle was immersed in a Ringer fluid containing 110 m*M* sodium chloride while the other was obtained after the concentration of sodium chloride was reduced to 55 m*M* by replacement with choline chloride. The dashed lines are extrapolated to the potential at which the ionic currents would equal zero. The calculation for the magnitude of ionic current was based on the assumption of a membrane capacitance of 6 μF./cm.[2]. The actual value of the capacitance enters the calculations only as a scale-factor for the ordinate and will not affect the extrapolation to + 37·5 mV. (110 m*M* sodium chloride) or + 22·5 mV. (55 m*M* sodium chloride). Note that the firing potential at − 45 mV. is not affected by the concentration of sodium ions. Although the method in itself cannot distinguish between currents carried by sodium or potassium ions, the results which followed experimental alterations of the Ringer fluid suggest that the sodium ion may carry a significant fraction of the current during the upstroke of the muscle fibre spike. For example, as shown in Fig. 3, reduction of the external concentration of sodium ion from 110 m*M* to 55 m*M* caused a decrease of 15 mV. in the extrapolated intercept as compared with the 16·5 mV. shift demanded by the resulting decrease in the sodium potential. On the other hand, analysis of other experiments clearly showed that increases of external concentration of potassium ions from 2·5 m*M* to 10·5 m*M* or of concentration of calcium ions from 1 m*M* to 10 m*M* have a negligible effect on this intercept, although the ionic current magnitudes were significantly modified. While these latter ions might be expected to alter the membrane conductances, they should not affect the sodium potential. In addition, the approximate, extrapolated zero-current potentials from the five records obtained from fibres immersed in 110 m*M* sodium chloride Ringer fluid range from + 38 to + 42 mV., and when substituted into the diffusion potential equation predict internal concentrations of sodium ions of 22–25 m*M*. These records were obtained from fibres isolated for at least 1 hr., and these concentrations seem quite consistent with published data.

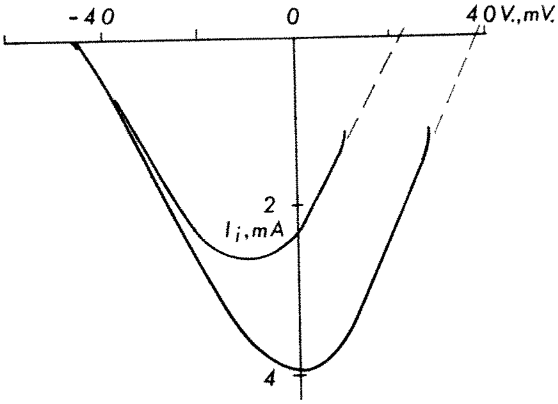

Fig. 3

Because the intercept at zero current behaves as described it has been tentatively assumed that this may be the sodium potential. If so, the ionic currents associated with this portion of the spike-potential should be carried predominantly by the sodium ion. It is recognized that the behaviour of this part of the voltage-current plot may be a fortuitous result of the chosen functions and this is being investigated.

ENLARGEMENT OF SALIVARY GLAND IN MICE TREATED WITH ISOPROPYLNORADRENALINE

By Dr. K. BROWN-GRANT

Department of Physiology, Medical School, Birmingham 15

SELYE *et al.*[1] have recently reported that large doses of *iso*propylnoradrenaline (*iso*proterenol) stimulate the growth of the salivary glands of the rat. In view of the similar sex dimorphism and the similar response of the submandibular glands of both rats and mice to sex hormones and thyroxine[2], the effect of this catechol amine on the glands of mice has been investigated.

Nineteen male albino mice of the Parkes strain (mean initial body-weight 30 gm., range 28–34 gm.) were used; 7 served as controls and the others were injected twice daily intraperitoneally with *iso*propylnoradrenaline sulphate (40 mgm. per 100 gm. body-weight in 0·2 ml. of water). On the fifth day of treatment, five of the animals died. The dose was reduced to 30 mgm. per 100 gm. body-weight and the treatment continued for a further two days. On the eighth day the control animals and the survivors of the treated group were injected subcutaneously with 4 μc. of carrier-free ^{131}I-iodide in a volume of 0·1 ml. and killed 2 hr. later. The external lacrimal, sublingual, submandibular and parotid glands were removed, weighed rapidly to the nearest 0·1 mgm. and one gland of each pair placed in 10 per cent neutral formol-saline for fixation. A serum sample was obtained and the second submandibular gland was dissolved in 3 N sodium hydroxide. Radioiodine contents were measured in an $M6$ liquid Geiger counter and the concentration ratio (counts/sec./100 mgm. gland: counts/sec./100 mgm. serum) was calculated.

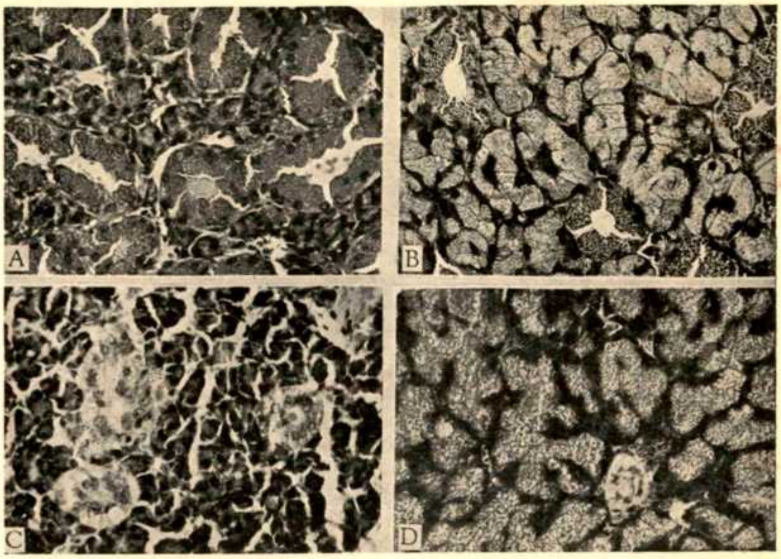

Fig. 1. 7-μ sections, stained hæmatoxylin and eosin. (× *c*. 200.) *A*, Normal mouse submaxillary gland. Note predominance of granulated tubules in the field; *B*, treated mouse submaxillary gland. Note increase in size of acinar cells. Granulated tubule size maintained. Cell granules are prominent; *C*, normal parotid gland. Small basophilic acinar cells; tubule cells show well marked striations with round central nuclei; *D*, treated parotid gland. Note acinar cell enlargement with displacement of nuclei. Ducts compressed with loss of basal striations in cells

The results obtained are shown in Table 1. Significant increases in the weight of the submandibular and parotid glands were observed in mice dying after 5 days treatment and in mice killed on the eighth day. The further increase between the fifth and eighth days was significant in the case of the parotid gland but not in that of the submandibular gland. In confirmation of the findings of Selye *et al.*[1], the weight of the external lacrimal gland was not affected by this treatment. The sublingual gland weight was not increased in these mice and the submandibular gland weight at the eighth day was only 150 per cent of the control value as compared to a parotid weight of 550 per cent of the control value. Selye *et al.*[1] state that the parotid, submandibular and sublingual glands were enlarged to approximately the same degree in female rats treated with a similar dose of *iso*propylnoradrenaline for 17 days, but do not give figures for the individual glands. The difference could be due to the difference in species, sex or duration of treatment.

Histological examination (paraffin embedding, 7-μ sections stained with hæmatoxylin and eosin) of the submandibular and parotid glands of all the control mice and of all those killed after 8 days treatment revealed marked differences. The most striking feature of both submandibular and parotid glands was a great increase in the size of the acinar cells; the cytoplasm was filled with basophilic secretory granules; the nuclei often appeared compressed and were displaced to the periphery of the acini. Intercellular canaliculi were prominent and contained material with the same staining properties as that seen in the major intralobular ducts. Intercalated ducts which are not obvious in the normal gland were prominent in the treated animals because of the distension of their lumina by secreted material. The condition of the major intralobular ducts differed in the two glands; the striated ducts of the parotid were found to be compressed when the diameter was measured from the base of the tubule cells. The lumen, however, was dilated with basophilic secretion; the tubule cells themselves were flattened, the normally round, central nuclei appeared as ellipsoids with their long axes parallel to the length of the tubule. The normal basal striations of the cytoplasm were much less obvious and in some cases absent. The convoluted granular tubules (serous tubules) of the submandibular gland which predominate in the normal male gland were less obvious in the treated animals because of the great increase in size of the acinar cells. Examination of individual tubules did not show any change in external diameter or in the size of individual tubule cells comparable with the changes in acinar cells. A possible increase in the number of large, intensely eosinophilic granules was suspected in some of the glands from treated animals; but considerable variation within both control and experimental groups and within the same gland made a decision on this point difficult. Sections stained by the periodic acid–Schiff method and counterstained with aniline blue and orange *G* showed that some acinar cells in the normal parotid contained periodic acid–Schiff-positive granules lying at the luminal borders of the cells. A faint positive reaction was observed diffusely in the cytoplasm of the majority of acinar cells in the treated gland. The normal submandibular acinar cells showed areas of periodic acid–Schiff-positive material in the cytoplasm; in the treated gland the acinar cell cytoplasm was uniformly positive; the contents of the ducts gave a strong positive

Table 1. GLAND WEIGHTS (MGM.) AND THE SUBMANDIBULAR GLAND/SERUM CONCENTRATION RATIOS FOR IODINE-131 IN NORMAL AND *ISO*PROPYLNORADRENALINE-TREATED MICE

Figures are means ± S.E.M. Not significant (N.S.) indicates a value for P of greater than 0·05 in the t test for the significance of the difference of group means

reaction. The mitotic proliferation reported by Selye *et al.*[1] in the rat was not seen in these mouse glands. Mitotic figures were searched for, but were extremely rare.

The histological picture is interpreted as showing an intense stimulation of the glands resulting in an increase in size of the acinar cells which are swollen with secretory material; many of the intralobular duct lumina are also distended with secretion. There is no histological evidence of a comparable stimulation of duct cells in the parotid glands or in the intercalated ducts, striated intralobular ducts or interlobular ducts of the submandibular gland. There is some evidence of stimulation of the cells of the serous tubules, which are not compressed like the cells of other ducts, and many show an increase in the number and size of their secretory granules. The gland/serum concentration ratio for radioiodide is not significantly altered (Table 1). This observation may be related to the histological evidence of stimulation of the convoluted granular tubules, as these are the elements in the gland which are thought to be responsible for the high concentration of iodide in the saliva and in the gland itself relative to the serum[3]. The maintenance of the normal gland : serum concentration ratio, despite the marked increase in the acinar cell mass, is also suggestive of a possible stimulation of the serous tubule cells.

No evidence of hyperplasia of the glands was seen in the present experiments, nor is it necessary to invoke this to explain the increase in weight. The relative width of the acinar cells in the normal and treated glands was measured in representative sections and was found to be in the range of 1 : 1·6–1 : 1·8. Assuming the cells to be cuboidal and the specific gravity to be unchanged, such an increase in size in cell dimensions would result in a weight ratio of about 1 : 4·9, roughly what was found in the parotid glands, where acinar cells predominate over tubules. The smaller increase in weight in the submandibular glands, despite an equally striking increase in the size of the acinar cells, may be due to the far greater proportion of the normal gland weight that is contributed by the tubules which do not increase in size during treatment with large doses of *iso*propylnoradrenaline. Although the weights of the sublingual and external lacrimal glands were not increased, histological examination showed that these glands, too, had been affected. There was evidence of a much less-marked and more variable increase in size of the acinar cells with the accumulation of secretory material within the cells and in the duct lumina.

The changes observed in the salivary glands of these mice are consistent with an intense, but not unexpected, stimulation of acinar cell secretory activity by these very large doses of *iso*propylnoradrenaline. This, rather than a sialoadenotrophic action of this compound, such as has been reported in rats[1], appears to be the most probable explanation for the dramatic changes in weight observed.

My thanks are due to Prof. J. Orr, Dr. F. Jacoby and Dr. Kathleen Hall for their advice, and to Mr. D. Varley and Miss Rita Hore, who prepared the sections and photomicrographs for me.

STIMULATION OF TURNIP YELLOW MOSAIC VIRUS PROTEIN PRODUCTION BY 2-THIOURACIL

By Dr. R. I. B. FRANCKI and Dr. R. E. F. MATTHEWS
Botany Department, University of Auckland, and Plant Diseases Division, Department of Scientific and Industrial Research, Auckland,

THE uracil analogue, 2-thiouracil, reduces the rate of multiplication of several plant viruses[1]. When tobacco mosaic virus multiplication is inhibited by 2-thiouracil, the analogue is incorporated into the virus ribonucleic acid (RNA)[2]. Both whole virus containing 2-thiouracil and RNA prepared from it by the phenol method[3] appear to be less infectious than normal virus. In the experiments reported here we have found that, while 2-thiouracil suppresses multiplication of turnip yellow mosaic virus (TYMV) nucleoprotein, it causes a spectacular increase in the production of virus protein shells containing no RNA. The analogue is not incorporated into the RNA of complete virus in detectable amounts.

The strain of TYMV used and the methods of inoculation and culture in Chinese cabbage plants have been described[4]. We have found that Chinese cabbage plants are much less susceptible to gross leaf injury and inhibition of growth by 2-thiouracil than many other species, such as tobacco. Plants to be treated with 2-thiouracil were sprayed daily with a 0·001 *M* solution of the analogue, controls being sprayed with water. To reduce variability in the sample, groups of 6–18 plants were used for each treatment and one or more disks were taken from each leaf and pooled at each time of sampling. In most experiments the disks were ground immediately after sampling and the sap pressed through muslin. The sap was then examined in a Spinco model *E* analytical ultracentrifuge either without further treatment or after heating at 55° for 5 min.—a treatment which destroys the integrity of the plant ribosomes. Sap from healthy Chinese cabbage plants sprayed with 2-thiouracil and heated in this way, shows no peaks sedimenting at the rates of the virus protein or nucleoprotein. In some of our early tests samples of leaf were frozen before examination. We abandoned this procedure, however, since we found that freezing may convert a substantial proportion of the empty protein shell fraction and a lesser amount of the nucleoprotein to a heterogeneous material sedimenting at about the same rate as the plant ribosomes.

Quantitative estimates of the concentration of components were made by measuring areas under the schlieren curves. Areas were corrected for radial dilution, but not for the Johnston–Ogston effect. Difficulty in assessing the correct base line in the schlieren patterns from crude plant extracts leads to significant ambiguity when the areas of the peaks are small. The base line is easier to determine when heat-clarified sap is used, but heat-treatment leads consistently to a slight reduction in the area of the empty protein shell peak. We do not yet know whether this reduction is due to error in base line determination or to destruction of a small proportion of the empty shells. However, this source of error is negligible for the major effects described here. Areas were translated into concentrations in mgm./ml. using experimentally determined factors for the virus protein and nucleoprotein. In some experiments an independent estimate of the virus nucleoprotein material was made by the serological–chromatographic procedure[5].

Earlier experiments[6] in which rather crude methods were used, had suggested that the ratio of virus protein to nucleoprotein in plants infected with TYMV was fairly constant, but our examination of heat-clarified sap in the ultracentrifuge has shown that this is not so. In normal infections the virus nucleoprotein fraction is the first detectable component (6–8 days after infection in inoculated leaves and 9–11 days in systemically infected leaves). The virus protein peak appears a few days later, and for several days thereafter the virus protein/nucleoprotein ratio rises, reaching a maximum of about 0·4–0·6 and then falling steadily to about 0·1–0·3.

Fig. 1 illustrates the substantial increase in the area of the virus protein peak that is brought about by appropriate treatment of plants with 2-thiouracil. Our evidence that the material constituting this increased peak is largely or entirely TYMV protein is as follows: (1) it has the expected sedimentation coefficient; (2) the material composing the peak is as stable to heating at 55° as the virus protein peak from untreated plants; (3) the peak, along with the virus nucleoprotein peak, is quantitatively removed by the addition of a slight excess of antiserum prepared by the injection of rabbits with highly purified TYMV B_1 nucleoprotein[4]; (4) both the ethanol-ammonium sulphate[7] and pH 4·8 (ref. 4) procedures for purifying TYMV are known to be effective in removing plant proteins and nucleoproteins. When TYMV is isolated by either of these methods from sap such as that shown by Fig. 1*A*, the ratio of the virus protein to nucleoprotein peaks remains substantially unchanged through all steps in the isolation; (5) when purified virus preparations made from infected plants suitably treated with 2-thiouracil are fractionated by sedimentation into dense cæsium chloride solutions[4], the opalescent band sedimenting in the position of the empty protein shell is greatly increased in amount relative to the B_1 nucleoprotein. The material isolated in this way has an ultra-violet absorption spectrum indistinguishable from the normal virus protein.

Under conditions where 2-thiouracil causes a large increase in the content of empty virus shells, it has no detectable effect on the areas of the plant ribosome peak, or the fraction I (ref. 8) protein peak.

The effect of 2-thiouracil treatment on the amounts of TYMV protein and nucleoprotein produced in the leaf depends strongly on the time after infection at which treatments are begun (Fig. 2). If spraying is started within a few days after inoculation, nucleoproduction is strongly suppressed, while protein production is not markedly affected. This leads to a large increase in the protein/nucleoprotein ratio, although there is a net decrease in the rate of production of total virus protein (empty protein shell + protein in the nucleoprotein fraction). If treatment is begun when the virus infection is well established, 2-thiouracil causes a striking rise in the production of empty protein shells. The production of nucleoprotein is not as strongly depressed as when treatments are started earlier. The net effect is a substantial increase over untreated plants in the content of total virus protein material.

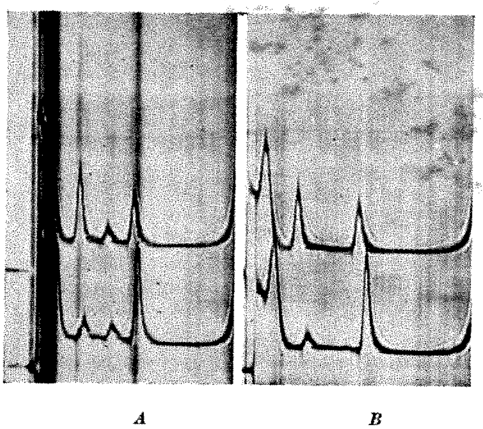

Fig. 1. Schlieren diagrams of expressed sap from Chinese cabbage plants infected with TYMV. *A*, untreated sap after centrifugation at 35,600 r.p.m. for 14 min.; *B*, sap heated to 55° for 5 min. and then centrifuged at 31,410 r.p.m. for 21 min. Plain cell (lower pattern) contains sap from control plants. Wedge cell (upper pattern) contains sap from plants sprayed daily with 2-thiouracil for 10 days. For Fig. 1*A* peaks in order from left are: (*a*) fraction I plant protein; (*b*) TYMV empty protein shell; (*c*) plant ribosomes; (*d*) TYMV nucleoprotein

Spraying infected plants daily with 0·001 *M* uracil beginning 13 days after inoculation causes an increase in the rate of production of virus nucleoprotein, but the protein/nucleoprotein ratio is not affected. Thus the availability of uracil may be a factor limiting TYMV production. If, however, plants are sprayed with a mixture of 2-thiouracil and uracil (both 0·001 *M*), uracil does not annul the effect of 2-thiouracil. Rather the production of excess protein shells reaches substantially higher levels than with 2-thiouracil alone. The stimulation of virus protein synthesis can, however, be halted by washing the leaves with water and stopping application of 2-thiouracil.

Experiments in which plants were supplied with sulphur-35 as inorganic sulphate, as described in ref. 4, suggest that the rapid increase in empty protein shells caused by 2-thiouracil is due to the formation of new protein rather than 'polymerization' of pre-existing sub-units of the virus shell. For example, in one test, two virus-infected plants, one

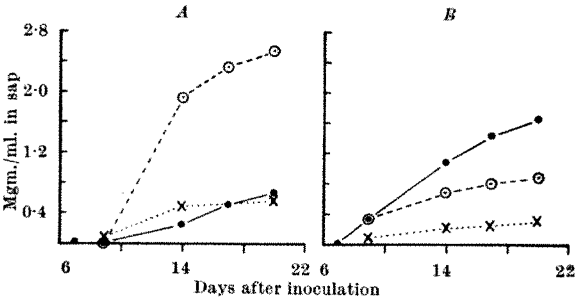

Fig. 2. Effect of 2-thiouracil on TYMV protein and nucleoprotein production. *A*, virus protein shells; *B*, protein in virus nucleoprotein; ●, control sprayed with water; ×, sprayed daily with 2-thiouracil beginning 1 day after inoculation; ○, sprayed daily with 2-thiouracil beginning 9 days after inoculation

of which had been treated with 2-thiouracil for 3 days, were placed in the sulphate solution labelled with sulphur-35 for 4 hr. before gathering. The protein in the isolated protein and B_1 nucleoprotein fractions had the following relative specific activities (expressed as c.p.m./mgm. protein): control protein, 7,570; control nucleoprotein, 4,570; 2-thiouracil protein, 42,500; 2-thiouracil nucleoprotein, 1,200. This differential labelling, together with the observed variations in the ratio of protein shells to nucleoprotein in untreated plants and the accumulation of protein shells following treatment with 2-thiouracil, all lend support to the view[4,9] that the empty protein shells are precursors of complete virus.

In all experiments in which concentrations of the virus components were measured in expressed sap, the nucleoprotein fraction, while consisting largely of the B_1 component[4], also included the B_2 and possibly the B_0 components. We have found that, by sedimenting purified virus preparations in the analytical centrifuge at high concentrations (10 mgm./ml.) in a medium of cæsium chloride of density = 1·36, the B_2 component migrates, as a peak with measurable area, ahead of the B_1 component. The concentration of B_1 in the preparation is estimated from the area of the peak obtained in a second run at lower concentration (2–3 mgm./ml.) in 0·1 *M* sodium chloride. Using this procedure, we have been able to estimate the ratio B_2/B_1. This ratio was consistently less in preparations from plants where empty protein shell was accumulating rapidly and where the rate of nucleoprotein production was reduced by treatment with 2-thiouracil. For example, in a control virus preparation where the ratio of protein to nucleoprotein was 0·25, the ratio B_2/B_1 was 0·042. The corresponding figures for a preparation from plants treated with 2-thiouracil for 4 days were protein/nucleoprotein 0·88; B_2/B_1 0·029. This reduction in the ratio B_2/B_1 would be consistent with the suggestion[4] that B_2 may be a stage in the assembly of complete virus from empty protein shells.

2-Thiouracil does not appear to be incorporated into the virus RNA. In one test where plants were treated with 2-thiouracil labelled with sulphur-35 (Amersham code *SJ*50) no significant radioactivity could be detected in either whole purified virus preparations or in the isolated B_1 component under conditions in which we would have detected incorporation of 2-thiouracil equivalent to 0·01 per cent of the virus uracil. In this experiment the ratio protein/nucleoprotein at the beginning of treatment was 0·19 and at time of collecting (after 8 days) was 0·73.

The reason why 2-thiouracil causes protein shells to accumulate is at present quite obscure. The phenomenon bears at least a superficial resemblance to the action of proflavine on certain viruses attacking *Escherichia coli*[10]. 2-Thiouracil may have its effect in part either by inhibiting virus RNA synthesis or, if virus RNA is made, by preventing its incorporation into the protein shell. However, neither of these effects could explain the appearance of a greater total of virus protein material in leaves treated with 2-thiouracil. Lack of incorporation of the RNA might be due to the production of either faulty RNA or faulty virus protein shells or both of these. As yet, we have no evidence as to whether the protein which accumulates is biologically functional or not.

It should be possible to determine whether free virus RNA accumulates at a rate equivalent to the increase in protein shells since after treatment for a few days with 2-thiouracil the amounts present would be about 0·5 mgm. of RNA per gm. fresh weight of leaf.

ROOT TEMPERATURE AND SYMBIOTIC NITROGEN FIXATION

By A. H. GIBSON

Division of Plant Industry, Commonwealth Scientific and Industrial Research Organization, Canberra

THE effect of physical environment on nodule formation and symbiotic nitrogen fixation has received little attention, although such factors as soil and air temperatures, light intensity and moisture conditions appear to be important. Investigation of the effects of these factors has begun, with the initial emphasis on effects of root temperature on symbiotic nitrogen fixation by *Trifolium subterraneum* (subterranean clover).

Hely (personal communication) has observed that during winter periods nodulated clover plants make poor growth compared with plants receiving combined nitrogen. Meyer and Anderson[1] have shown that moderately high temperatures specifically inhibit nitrogen fixation, although Mes[2] suggested that their conclusions should be restricted to subterranean clover. The aim of this investigation was to find the most effective combinations of host and bacterial strain suitable for the various ranges of environmental conditions found in the field. This article reports two experiments with two varieties of *T. subterraneum* inoculated with each of two strains of *Rhizobium trifolii*.

The plants were grown on mineral nutrient agar, free from available combined nitrogen, the enclosed tube technique[3] being modified so that only the roots grew inside the tube. Two days after sowing surface-sterilized pre-germinated seeds, the plants were either inoculated or left uninoculated as controls; 13 days later the inoculated plants were well nodulated. At this time a uniform population of plants was selected, and ammonium nitrate added to the controls. One-fifth of the plants were collected for initial nitrogen-level determinations, and the remainder transferred to a controlled environment unit in which the tubes were suspended in temperature-controlled water-baths (temperature variation ± 0·3 deg. C. in the tubes). The source of light was a bank of 'Warm White' fluorescent, and incandescent, tubes giving an intensity of 1,000 ft.-candles, and a photoperiod of 16 hr. For all plant tops the phototemperature was 22–23° C., and the nyctotemperature 10–11° C. The tubes were re-filled with sterile nutrient solution when necessary and ammonium nitrate added to the controls at regular intervals to give the following amounts of combined nitrogen: 4 mgm. for root temperatures 5° and 9·5° C., and 6 mgm. for 14° and 18° C. in experiment 1 ; 9 mgm. for 18°, 22°, 26° and 30° C. in experiment 2. The ten replicates of each treatment were collected after growth for 20 days in the unit, and the dry weights and total nitrogen determined.

The values in Table 1 express nitrogen fixed during the temperature treatments as a percentage of the combined nitrogen assimilated by the control plants; these values provide an index of the effectiveness of the symbiosis[4]. In experiment 1, the Tallarook controls at 18° C. appeared to be slightly deficient in nitrogen, although the amount assimilated was less than that added. For experiment 2, higher levels of ammonium nitrate were added to the controls, but the amounts assimilated were probably excessive, as shown by: (1) a percentage nitrogen of 4·3–4·7 in all control treatments compared with a normal level of 3–3·5 per cent; and (2) a close similarity in total dry weight of the controls and the most effectively nodulated treatments (Tallarook inoculated with *TA*1). The excessive assimilation of combined nitrogen probably explains the generally lower values for the index of effectiveness in experiment 2, relative to experiment 1, in Table 1.

At root temperatures of 5° and 9·5° C., Tallarook inoculated with strain *TA*1 is able to fix nitrogen as effectively as the controls can assimilate combined nitrogen, whereas the remaining three combinations of host and strain are less effective. As the temperature rises, the effectiveness of these three associations improves. Above 22° C., the effectiveness of nitrogen fixation by strain *NA*30 on both varieties is reduced considerably, while the effectiveness of strain *TA*1 remains comparatively constant. The results obtained with strain *NA*30 are similar to those reported by Meyer and Anderson[1], who also used this strain (personal communication). However, the results with strain *TA*1 suggest that their postulate that moderately high temperatures specifically inhibit symbiotic nitrogen fixation requires further elucidation.

Table 1. EFFECTIVENESS OF SYMBIOTIC NITROGEN FIXATION AND COMBINED NITROGEN UPTAKE (MGM. AMMONIUM NITRATE – NITROGEN/PLANT) AT DIFFERENT ROOT TEMPERATURES

Root temp. (°C.)	Uptake of ammonium nitrate		Index of effectiveness			
			Variety Tallarook		Variety Dwalganup	
	Tallarook	Dwalganup	Strain *TA*1	Strain *NA*30	Strain *TA*1	Strain *NA*30
Exp. 1						
5·0	0·99	0·90	97·6	49·7	42·6	50·0
9·5	2·67	2·07	104·2	72·8	58·4	67·7
14·0	4·46	3·58	90·2	79·7	65·1	75·8
18·0	4·55	3·76	111·0	86·4	63·8	82·8
Exp. 2						
18·0	5·96	4·83	72·4	56·1	45·1	57·2
22·0	9·05	6·89	74·3	51·0	48·7	49·1
26·0	7·41	6·54	85·8	32·7	39·7	35·7
30·0	7·00	2·68	74·9	9·9	58·8	18·8

The index of effectiveness is derived from $\frac{\text{nitrogen fixed}}{\text{ammonium nitrate uptake}} \times 100$

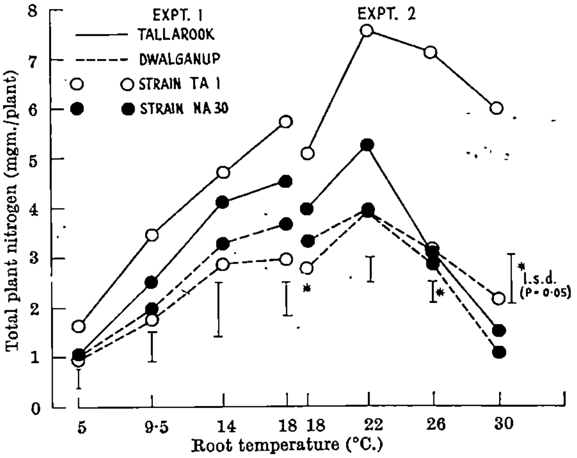

Fig. 1. Effect of root temperature on total plant nitrogen

*Owing to significant differences between error variances, no L.S.D. values are shown for the treatment means at 18° C., nor for the Tallarook means at 26° and 30° C. in experiment 2.

It would appear that the temperature at which nitrogen fixation is affected, relative to plant growth on combined nitrogen, may depend on the bacterial strain, or at least on the host × strain combination. However, it is possible, as found with these experimental conditions, that fixation of nitrogen by some combinations of host and strain is relatively insensitive to higher temperatures, when compared with the uptake of combined nitrogen; for example, Dwalganup controls made poor growth at 30° C., yet the index of the effectiveness of nitrogen fixation by this host, inoculated with *TA*1, remains similar to that at 18–26° C.

Jones and Tisdale[5] showed that four species of nodulated legumes differed in their tolerance of high soil temperatures. Mes[2] observed that maximum nitrogen fixation by several species of nodulated legumes was attained at different day temperatures, and also at different night temperatures. In neither case were the effects of bacterial strain examined. In the present investigation, temperature influenced the relative effectiveness of two strains of *Rhizobium trifolii* on two varieties of the one host species (Fig. 1). With the variety Tallarook, there is a marked divergence in the level of total plant nitrogen for the two strains of *Rhizobia* as the root temperature rises above 22° C. In addition, there is a temperature × strain interaction with the variety Dwalganup, with *NA*30 being the better strain below 22° C., and strain *TA*1 superior at 30° C. This reversal of the order of effectiveness of the two strains on Dwalganup has been observed repeatedly.

The demonstration of temperature × strain, and host × strain, interactions within the species *T. subterraneum* indicates that these three factors should be considered in the selection of strains of *Rhizobia*, if the full potential of the legume-rhizobia symbiosis is to be attained.

LETTERS TO THE EDITORS

COSMOLOGY

An Unsteady Universe with Excess of Charge

RECENTLY, Lyttleton and Bondi[1] put forward the suggestion that the outflow of matter in the universe is caused by a net charge on the hydrogen atom, and that in order for the universe to remain steady in the large, there is creation of matter. This analysis was simplified by me[2] with the aid of Watson's creation potential[3].

Suppose, however, that the universe is not steady, but is uniform, being composed of hydrogen atoms of mass m and charge e. Following the arguments of Milne[4], if the velocity of any particle, the position vector of which with respect to the origin is $\mathbf{r}$, is $\mathbf{r}/t$ each particle in a Newtonian system can equally be regarded as the centre of the universe. The associated acceleration is:

$$\frac{d\mathbf{v}}{dt} = (\mathbf{v} \cdot \nabla)\mathbf{v} + \frac{\partial \mathbf{v}}{\partial t}$$

$$= (\alpha^2 - \alpha)\frac{\mathbf{r}}{t^2}$$

The proof is given by Milne for the case $\alpha = \frac{2}{3}$, and the extension is obvious.

Maxwell's modified equations are[3]:

$$\nabla \times \mathbf{E} + \frac{\partial \mathbf{B}}{\partial t} = 0, \quad \nabla \cdot \mathbf{B} = 0,$$

$$\nabla \times \mathbf{H} - \frac{\partial \mathbf{D}}{\partial t} = \mathbf{J} - \frac{1}{\mu_0}\nabla N, \quad \nabla \cdot \mathbf{D} = \rho + \varepsilon_0 \frac{\partial N}{\partial t}$$

If a solution be taken for which $\mathbf{H}$ is zero as previously[2];

$$\nabla \times \mathbf{E} = 0, \quad -\frac{\partial \mathbf{D}}{\partial t} = \mathbf{J} - \frac{1}{\mu_0}\nabla N,$$

$$\nabla \cdot \mathbf{D} = \rho + \varepsilon_0 \frac{\partial N}{\partial t}$$

Eliminating N, it follows that:

$$\nabla(\nabla \cdot \mathbf{D}) - \mu_0\varepsilon_0 \frac{\partial^2 \mathbf{D}}{\partial t^2} = \nabla \rho + \mu_0\varepsilon_0 \frac{\partial \mathbf{J}}{\partial t}$$

$$= \nabla \rho + \mu_0\varepsilon_0 \frac{\partial}{\partial t}(\rho\mathbf{v})$$

$\mathbf{v}$ being the flow velocity of the electric charge density.

If m be the mass of a hydrogen atom, then:

$$m\frac{d\mathbf{v}}{dt} = e^*\mathbf{E} = e^*\frac{\mathbf{D}}{\varepsilon_0}$$

where:

$$e^* = e\left(1 - \frac{\gamma m^2 4\pi\varepsilon_0}{e^2}\right)$$

that is, if the electric repulsion between two particles is greater than the gravitational attraction between them, e^*/e is positive, and vice versa.

It follows, therefore, that:

$$\mathbf{D} = \frac{\varepsilon_0 m}{e^*}\frac{d\mathbf{v}}{dt} = \frac{\varepsilon_0 m}{e^*}(\alpha^2 - \alpha)\frac{\mathbf{r}}{t^2}$$

This field satisfies $\nabla \times \mathbf{E} = 0$ identically.

On the assumption that the universe is uniform in the large, $\nabla \rho$ vanishes; also $\nabla \cdot \mathbf{r} = 3$ and so $\nabla(\nabla \cdot \mathbf{r}) = 0$.

$$\mu_0\varepsilon_0 \frac{\partial}{\partial t}\left(\rho\,\alpha\frac{\mathbf{r}}{t}\right) = \frac{\varepsilon_0 m}{e^*}(\alpha^2 - \alpha). - \mu_0\varepsilon_0\frac{6\mathbf{r}}{t^4}$$

whence:

$$\rho = \frac{2\varepsilon_0 m(\alpha - 1)}{\varepsilon^* t^2}$$

The rate of production of charge per unit volume is given by:

$$\nabla \cdot (\rho\mathbf{v}) + \frac{\partial \rho}{\partial t} = \nabla \cdot \left\{\frac{2\varepsilon_0 m(\alpha - 1)\alpha\mathbf{r}}{e^* t^2}\right\} - \frac{2\varepsilon_0 m(\alpha - 1).2}{e^*\ t^3}$$

$$= \frac{2\varepsilon_0 m}{e^* t^3}(\alpha - 1)(3\alpha - 2) = \frac{\rho}{t}(3\alpha - 2)$$

The rate of creation of atoms per unit volume is, of course, obtained by dividing by e. The cases where the production-rate are zero $\alpha = 1$, and $\alpha = \frac{2}{3}$. In the first case, the acceleration of the nebulæ $\frac{d\mathbf{v}}{dt}$ is zero[5] which would correspond here to the electric repulsion being exactly equal and opposite to the gravitational attraction, thus balancing it out. The second case corresponds to Milne's Parabolic Universe[6].

The recession-rate of the nebulæ is given also by $\mathbf{v} = \frac{\mathbf{r}}{\tau}$, where τ is the inverse of Hubble's constant. Thus, the time at present is $\alpha\tau$, and the present rate of production of charge density is $\rho/\tau\left(3 - \frac{2}{\alpha}\right)$. Corresponding to this is a present rate of production of mass density $\frac{\rho_m}{\tau}\left(3 - \frac{2}{\alpha}\right)$ where ρ_m is the present mass density. Now

$$\rho_m = \frac{m}{e}\rho = 2\varepsilon_0 m^2 \frac{e}{e^*}\frac{\alpha - 1}{t^2}$$

and at present,

$$\rho_m = 2\varepsilon_0 m^2 \frac{e}{e^*}\ \frac{\alpha - 1}{\alpha^2\tau^2}$$

There is experimental evidence[7] that:

$$\frac{8}{3}\pi\gamma\rho_m\tau^2 = U^{-1}$$

where U is a number the value of which is about unity and so it follows that:

$$\frac{e^2}{4\pi\varepsilon_0\gamma m^2} = \frac{4}{3}\ U\frac{\alpha - 1}{\alpha^2} + 1$$

The left-hand side is the ratio of electric repulsion to gravitational attraction, and must be positive, and so $\frac{4}{3}U\frac{(1 - \alpha)}{\alpha^2} < 1$. Now e is determinate in principle as indicated by Lyttleton and Bondi, and ρ_m and τ (and hence U) are also determinate from astronomatical observations. It follows, therefore, theoretically that α can be found, and hence the present rate of production of matter.

The observations made at time t of matter at a distance R, will refer to the matter at a time $t - R/c$. It follows, therefore, that the observed mass density at a distance R is:

$$2\varepsilon_0 m^2 \frac{e}{e^*}\frac{\alpha - 1}{(\alpha\tau - R/c)^2} = \rho_0\left(1 - \frac{R}{\alpha c\tau}\right)^{-2}$$

where ρ_0 is the local mass density at present. Also the observed recession velocity is:

$$\frac{\alpha R}{\alpha\tau - R/c} = \frac{R}{\tau}\left(1 - \frac{R}{\alpha c\tau}\right)^{-1}$$

Both these quantities, the observed mass density and the observed recession velocity, are in principle obtainable (albeit the experimental techniques are not good enough at present) and so α is obtainable in principle, and a test of this theory will be possible once the data are known with sufficient accuracy.

ASTRONOMY

The Alpha Virginis (Spica) Nebula

An extensive ultra-violet nebula surrounding Spica has been reported by Kupperian, Boggess, and Milligan[1]. Their rocket-borne photon counters yielded an isophotal map of roughly circular extent 22° in diameter, increasing in brightness from the outside towards Spica but reaching the instrumental saturation-level for the central area. If the nebula were due to Lyman-α radiation it would be reasonable to assume that H_α should also be detectable, but no nebula has ever been detected by conventional photographic means. This may have been due to the fact that the strong image of Spica drowns the faint nebula close to the star. On the red plates of the Palomar Sky Survey, the over-exposed image of Spica covers more than 10 min. of arc, while on the blue plates it is nearly three times larger in diameter. The spectrum of Spica itself does not show H_α in emission[2].

Recently, Johnson[3] reported negative results in H_α of the nebula by means of direct and spectroscopic exposures centred on the brightest ultra-violet isophote about 10 min. of arc west of Spica.

In order to examine the area immediately surrounding the star a number of long exposures have been taken during the past 18 months by means of a novel device which might be called a 'stellar coronagraph', attached to the 30-in. refractor at Allegheny Observatory. This device, to be described in detail in a later communication, prevents the stellar image from reaching the emulsion and obscures a circular area 1 mm. (14·6 sec. of arc) in diameter at the focal plane, thus completely eliminating the over-exposed stellar image and halation pattern. To cover the range of H_α, Eastman 103*a*-*E* plus Corning 2403 filter was exposed to a limiting stellar magnitude of $m_{pg} \approx 17$. A few blue exposures on 103*a*-*O* without filter were also taken. The useful field is only 6 × 8 min. of arc with the 14·6 sec. diameter blank space at the centre. None of the exposures reveals any trace of nebulosity.

This method looks promising for detecting circumstellar envelopes and faint companions close to bright stars and should yield best results on large reflectors with large plate scales.

It is a pleasure to thank Dr. N. E. Wagman for making the telescope available for these studies.

GEOPHYSICS

Height of Night-time *F* Layer Irregularities at the Equator

It has been established by observations at low latitudes that there exists near the equator a belt in the *F* region in which large irregularities in electron density give rise to equatorial spread *F*[1] severe radio star scintillations[2] and the scatter of radio waves[3]. Work by Hewish[4] and Briggs[5] on extra-terrestrial radio sources shows how the height of the irregularities may be inferred from observations of the diffraction pattern on the ground. But the methods used are rather indirect, and therefore subject to some uncertainty. More recently Cohen and Bowles[6], using radar techniques, arrived at an estimation of irregularities of height for equatorial locations. It is not certain that these irregularities are to be identified with those responsible for satellite and radio star scintillation.

Work on these disturbances now being pursued at University College, Ibadan, and at the University of Ghana, Accra, shows that the irregularities in the pattern on the ground are elongated in the direction of the Earth's magnetic field, that the axial ratio is greater than 6:1, and that the smaller dimension is of the order of 0·5 km. (J. R. K. and G. S. K., unpublished). These results are deduced from the study of satellite and radio star transmissions through the disturbed region. It is desirable to determine the heights of the irregularities by a direct method. The procedure adopted consists in the observation at two separated stations of the diffraction pattern produced on the ground when the radio transmissions from an Earth satellite pass through the irregularities. The velocity of the pattern over the ground is determined, and by relating this velocity to the known height and velocity of the satellite, it is possible to determine the effective height of the diffracting screen. Since the velocity of drift of the diffracting screen itself is known to be of the order of 150 m./sec. (J. R. K., unpublished) it can be neglected without introducing an appreciable error.

The observations were made at Legon, near Accra, Ghana (5° 38′ N.; 0° 11′ W.), and the satellite used was *Tiros II* (1960 π 1). Since its apogee and perigee distances are 724 and 624 km. respectively, it is normally above the electron-density maximum in the *F* layer. The orbit is inclined to the equator at an angle of 48·6°. The signal used was the transmission on 108·03 mc./s. At each station the signal was received on a half-wave dipole, and fed to a crystal-controlled converter ahead of a Collins type *R*.390*A*/*URR* radio receiver. To achieve a satisfactory signal to noise ratio it was necessary to employ a bandwidth of 100 cycles per second. Tuning was done manually at both receivers throughout each observation. In each case the receiver *B.F.O.* was used to give a 2,000 c.p.s. note, which was transmitted via telephone cable to a central recording location. The amplitudes of the signals were then displayed on a double-beam oscilloscope and recorded photographically. A number of observations were made with an east–west base-line 1 km. in length. Later a 2·4 km. base-line was used, inclined 48° to the equator in the plane of the satellite orbit. Observations were limited to night-time passes in the period June 21–July 13, 1961.

If the irregularities occur in a thin layer at a height z and the satellite is moving horizontally at a height h and a velocity V, it can be shown that the diffraction pattern will move across the ground with a velocity $V\frac{z}{h-z}$ (ref. 7). In the case of a satellite moving in an elliptical orbit around the Earth, the expression is more complicated; but the velocity and direction of movement of the pattern on the ground can still be derived from a knowledge of the orbit. The time-shifts observed in the fading at the two aerials depend on the relative direction of the velocity of movement of the pattern, the line joining the two aerials, and the direction of elongation of the pattern on the ground. The irregularities have been assumed to lie along the magnetic lines of force and, to a first order of approximation, to be infinitely elongated.

If the layer of irregularities is not thin, the form of the pattern will change slowly as the pattern moves across the ground, in a manner depending on the thickness. This will cause the maximum correlation of the signals at the two aerials to be less than unity. A further decrease will occur since the pattern is not infinitely elongated and the two aerials do not lie precisely along the direction of motion of the pattern. From observations of this decrease with different aerial orientations, it is in principle possible to separate these two effects and determine the thickness as well as the height of the layer of irregularities. In practice, due to the limitations of the equipment available, the results obtained even with the aerials lying almost along the direction of motion of the pattern were not accurate enough to give more than an upper limit to the thickness. The decrease in correlation also reduces the measured time-shift slightly, and a correction was applied for this.

The rate of fading of the signals was normally of the order of 5 cycles per second during periods of scintillation when measurements were made. Time-delays found over the two paths were about 0·2 and 0·4 sec. The records were normally taken for about 5 sec., and were read at intervals of 20 m.sec. Cross- and auto-correlation functions were calculated for the amplitudes of the signals received at the two aerials. Ten records were analysed, and the results are summarized in Table 1.

Table 1

Date	U.T.	Distance	Direction of irregularities observed	Height of base of *F* layer	Height of irregularities
22/6/61	22:01:03	1,169	1° W. of N.	350 km.	424 km.
22/6/61	22:02:01	1,658	6° E.	350	401
23/6/61	20:56:04	1,171	37° E.	360	416
24/6/61	21:27:02	913	34° W.	300	402
24/6/61	21:29:00	1,171	8° W.	300	396
24/6/61	21:30:06	1,545	7° E.	300	380
9/7/61	02:33:54	697	151° E.		395
10/7/61	01:22:30	788	9° E.		427
12/7/61	00:51:07	415	12° E.	260	354
12/7/61	00:52:07	292	46° E.	260	314

The distance given in column 3 refers to the distance along the ground from the observer to the point vertically below the irregularities observed. Column 5 shows the virtual height of the base of the *F* layer from an ionogram taken at Accra at the time of the observation. On all occasions on which satellite scintillations were observed, spread *F* and radio star scintillation were also present. It will be noted that the effective height of the irregularities always lies between 50 km and 100 km. above the base of the *F* layer. The value of height given above may be compared with the results of Cohen and Bowles[6], who found that the irregularities which they observe lie at or near the base of the *F* layer.

From the maximum values of the cross-correlations observed the elongation of the irregularities is found to be greater than 7 to 1, and the thickness of the scattering layer to be less than 120 km.

The programme of research of which this forms a part is financed by the Air Research and Development Command of the U.S. Air Force under contract No. *AF* 61 052–421.

A Method of Estimating Ionospheric Absorption Heights From Recovery Times

It is generally agreed that the absorption of radio waves in the ionosphere occurs at heights below about 100 km. In a particular instance it is usually possible to deduce the approximate height by indirect reasoning. For example, Hultquist[1] has used indirect evidence to place the abnormal absorption which follows intense solar flares at heights as low as 50 km. As yet there are too few direct measurements (using rockets) to provide a complete and consistent picture. This communication suggests a new method of estimating the height of the regions responsible for abnormal absorption of the kind associated with auroral disturbances.

Fig. 1 shows two examples of absorption as recorded by a riometer operating at a frequency of 30 Mc./s.

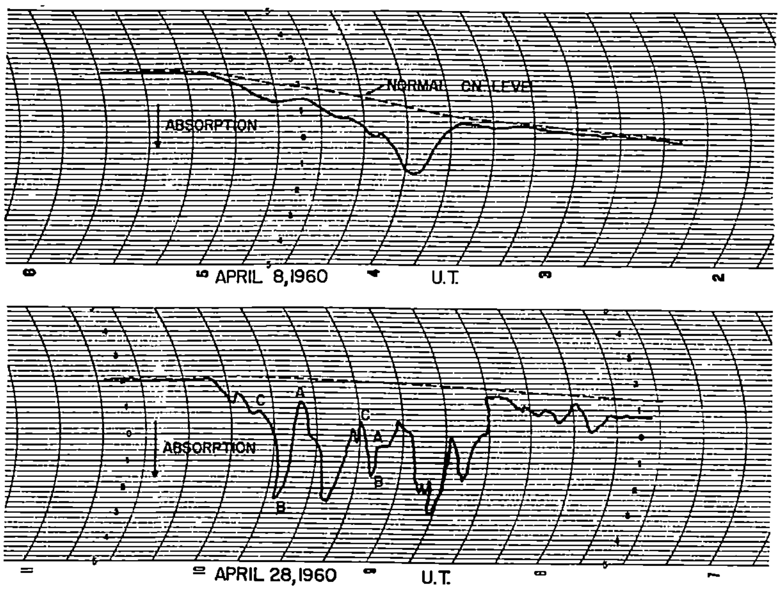

Fig. 1. Typical riometer records during abnormal disturbances. The upper trace shows a weak disturbance. The bottom trace was obtained during a severe disturbance

In each case the normal level of the cosmic noise signal in the absence of absorption is shown by the broken line. Sudden onsets of absorption (marked *AB* in Fig. 1) are frequently followed by rapid recoveries (*BC*). If it is assumed that the ionizing agency ceases to operate at the instant of peak absorption the recovery can be used for estimating the height of the region. The method depends on the fact that the absorption (expressed in decibels) suffered by a radio wave in the lower ionosphere is proportional to the number of electrons encountered (per unit area of the wave-front) in the absorbing region and is a function of the collisional frequency of the electrons.

Appleton investigated the disappearance of ionization in the lower ionosphere[2]. For small variations the ionization (electron density) should decay exponentially with a time constant:

$$T = (2\alpha N)^{-1} \text{ sec.}$$

where N is the average electron density, and α is an effective recombination or loss-rate coefficient. The quantity T is also known as the relaxation time of the ionospheric region concerned. For the present purpose it is assumed that the absorption occurs in a layer having a thickness of about one scale height which is taken to be 6·5 km. throughout the region of interest.

The electronic collisional frequencies given by Chapman and Little[3] were used to deduce electron densities required at various heights and were combined with the values of α given by Rumi[4] for day-time and night-time conditions to calculate the relaxation times (for 1 decibel of absorption) at various heights in the lower ionosphere. The relaxation times are plotted as a function of height in Fig. 2. In order to use the graphs it is necessary first to divide the observed time constant by the average absorption (expressed in decibels). Clearly, the observation would be meaningful only if the decay were measured over a change in absorption that represents only a small part of the total absorption present. There is an ambiguity in the heights deduced from Fig. 2; but this ambiguity usually can be resolved by reasoning based on the general characteristics of the regions concerned and of the absorption event. Heights deduced by the method outlined here have been compared with those determined by means of a three-frequency riometer method[5] and found to be in good agreement. I am indebted to Dr. A. Kavadas for very useful discussions and to Dr. P. A. Forsyth for valuable suggestions during the course of this investigation.

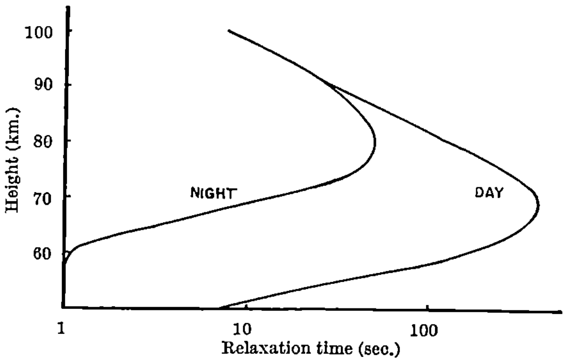

Fig. 2. Relaxation times as a function of height

PHYSICS

Ignition of Gas by Sparks produced by breaking Wires at High Speed

INVESTIGATIONS of the conditions for ignition of inflammable gas by electrical sparking have usually been carried out with discharges produced in one of two ways: (i) by discharging a capacitor charged to a high voltage between thin fixed electrodes separated by several millimetres; (ii) by breaking low-voltage circuits at the contacts of a mechanical switch (or 'break-flash'). It has been found that less electrical energy need be dissipated in the discharge to ignite the gas if the first of these methods is adopted; for example, an 8·3 per cent mixture of methane in air can be ignited by about 0·3 mJ. by the first method, whereas an energy of about 2 mJ. is required if the second method is used.

However, recent work both in Great Britain and in the U.S.S.R. has made use of the discharge which results when a wire carrying a current is broken in gas. The first experiments in this laboratory made use of comparatively thick wires (0·022 in. and 0·012 in. in diameter), broken so that their ends separated at about 400 cm./sec.; this is not very different from the speed of separation of electrodes of the standard break-flash[1] used in statutory testing of electrical apparatus for intrinsic safety. The currents and energies necessary to ignite gas in these conditions were only slightly smaller than those necessary with the standard break-flash. However, Berz[2] has found that, if very fine wires are broken at about the same speed, the minimum igniting currents become markedly smaller, and that they fall as the diameter of the wire is reduced. He showed that for 0·001-in. diameter tungsten wire the minimum igniting energy for an 8·3 per cent mixture of methane in air is comparable with that indicated by high-voltage experiments. He concluded that such substantial reductions in minimum igniting-energy could be obtained only when the 'electrodes' (that is, the broken wire-ends) were small compared with the critical size of the initial flame kernel in the gas (see, for example, Lintin and Wooding[3]).

It seemed likely, however, that the quenching effect of bulky electrodes could be reduced if they were rapidly removed from the kernel of the growing flame, and that the minimum igniting energies indicated by high-voltage experiments might be approached by breaking thick wires, provided that the speed of separation of the wire-ends after the break was made sufficiently high. It has been known for some time that variations in the speed of separation of electrodes of the standard break-flash apparatus (usually operated at about 300 cm./sec.) have an effect on the minimum igniting currents obtained with it, but we are not aware of previous experiments at much higher electrode speeds. Separation speeds of about 2,000 cm./sec. have now been achieved with a breaking-wire apparatus, partly based on a method developed by Gavril'chenko[4], in which a previously notched copper wire is broken by being stretched between pairs of rollers rotating at different speeds. The machine, an early model of which will be described elsewhere, differs from that of Gavril'chenko in that the length of wire stretched is comparatively long (about 35 cm.). As the wire is stretched, elastic energy is stored in it; when the wire breaks this is converted into kinetic energy and the ends of the wire separate rapidly. Although the speed of separation is substantially unaffected by the length of wire stretched, the distance over which this speed is maintained is approximately proportional to the length of wire, and in the present apparatus the separation speed of some 2,000 cm./sec. is maintained for a few millimetres.

Tests show that, although the wire is bulky (diameter 0·012 in.) compared with the wires broken by Berz, similar minimum igniting currents are obtained. Thus for a particular set of circuit conditions, a minimum igniting current of 110 m.amp. is obtained with the machine, compared with 110 m.amp. obtained by Berz for 0·005-in. steel wire, 95 m.amp. for 0·001-in. platinum wire, 82 m.amp. for 0·001-in. tungsten wire, and 185 m.amp. for the standard break-flash apparatus.

Further experiments in which notched wires 0·012 in. in diameter were broken manually (by anchoring one end and pulling the other with a pair of pliers) indicate even smaller minimum igniting currents of about 100 m.amp. for the same circuit conditions. It has not yet been possible to reproduce this manual process in a mechanized form, and further investigations are in progress.

These experiments suggest that it may be possible to design a breaking-wire apparatus which will be completely automatic and which will yield minimum igniting energies comparable with those indicated by high-voltage experiments. From a more fundamental point of view, they confirm that disturbance of the growing flame kernel by the electrodes plays a part in increasing the minimum energy necessary for ignition. If this disturbance is reduced, either by using very fine wires as in Berz's experiments, or by removing the electrodes rapidly from the flame kernel as in those reported here, energies approaching the minimum may be achieved.

Damping without Influence on Frequency

IN a recent communication[1], R. Parks and L. Maunder have directed attention to the fact that the period of oscillation of a gyrostat is not affected by damping if this were applied to both axes in a certain ratio (equal to the ratio of the moments of inertia of the uncoupled axes).

It is possible to re-formulate this condition as one of equal loss angles of the energy stores; with proper interpretation the same interesting and potentially useful result holds for ordinary (non-gyroscopic) systems and it can be extended to systems with more than one degree of freedom.

For a system with one degree of freedom the assertion will appear as an obvious conclusion from the Parks–Maunder result if we follow the approach of ref. 2, for there it is shown how the system considered by these authors can be transformed into a dynamically equivalent system consisting of a mass and a spring which are both subject to damping. The argument is based on the fact that, 'seen' across a gyrostatic coupler, a mechanical impedance Z looks like an admittance:

$$Y = Z/C^2n^2 \qquad (1)$$

where Cn is the moment of momentum of the gyrostat rotor around its axis of rotation. From this it follows that the mass impedance Bp attached to axis 2 of the gyrostat appears from axis 1 as the admittance $D_2p = Bp/C^2n^2$ of a spring; the viscous damper of constant c_2, which is linked co-resistively[3] to the mass, transforms into a viscous damper of constant $K_2 = C^2n^2/c_2$, which is linked co-yieldingly[3] to this spring. As the combined impedance of the uncoupled axis 2 amounts to $Bp + c_2$, we need not in fact even evaluate these individual components but can write directly from equation 1 the value of the impedance which the coupler transfers to axis 1 as $C^2n^2/(Bp + c_2)$. The governing equation for axis 1 then reads:

$$Ap + c_1 + \frac{C^2n^2}{Bp + c_2} = 0 \qquad (2)$$

This is, of course, equivalent to the equation derived in ref. 1 by purely algebraic manipulation.

To prove the general assertion, assume first that we deal either with a non-gyroscopic system consisting of masses and springs only, or with a gyroscopic system which, according to ref. 2, can be transformed into an equivalent system of this kind. Let $p_l = j\omega_l$ be one of the n frequencies for which the governing equations for this loss-less system are identically fulfilled. The value ω_l enters these equations only via the expressions for the mass impedances $Z_{mlh} = p_l m_h = j\omega_l m_h$ or the spring admittances $Y_{slh} = p_l D_h = j\omega_l D_h$, or via the reciprocals.

The corresponding expressions for the damped system are:

$$Z'_{mlh} = p_l m_h + K_h = p_l m_h + \alpha m_h, \text{ say, and}$$
$$Y'_{slh} = p_l D_h + x_h = p_l D_h + \alpha D_h \qquad (3)$$

for the conditions considered, where α is a constant, usually positive. It will be seen that for values $p'_l = j\omega_l - \alpha$, we get:

$$Z'_{mlh} = (j\omega_l - \alpha)m_h + \alpha m_h = Z_{mlh}$$
$$Y'_{slh} = (j\omega_l - \alpha)D_h + \alpha D_h = Y_{slh} \qquad (4)$$

This means that for this particular value of the complex frequency the coefficients of the governing equation(s) for the damped system are the same as for the undamped system. These equations are therefore solved by the same set of complex phasors as before, and the new case differs from the old one merely in so far that these phasors now describe a damped oscillatory motion of the form u_l = real part of U_l. exp($j\omega t$). exp($-\alpha t$) instead of U_l.exp($-j\omega t$).

If it is not possible or not desirable to transform a gyroscopic system into an equivalent non-gyroscopic system we have to consider the contributions arising from the gyroscopic coupling terms, that is, in the present notation from terms due to asymmetrical mutual coupling impedances of the form $Z_g = \pm C^2 n^2$. These impedances do not change when damping is added to the system nor—being independent of frequency—are they influenced by the change from p_l to p_l'. Hence the conclusion reached from equations (4) is not disturbed and the assertion remains valid.

Cryoscopic Effect of Separation and Concentration of Solutes

The normal method of concentrating a substance in solution is by distillation. In the course of certain experiments it was found that it is possible to do so to a certain extent by refrigeration.

A column of skim milk in a 250-ml. cylinder was frozen between −5° and −10° C. The frozen column was taken out and allowed to thaw at room temperature (24°–27° C.) in about 2·5 hr. The melted column showed a graded separation, ranging from solid concentration at the bottom to a thin, watery layer at the top. Portions of 10 ml. were carefully collected from the top and bottom of the column with the least possible disturbance, and analysed for total solids and milk sugar.

Table 1. CONCENTRATION OF SKIM MILK BY CRYOSCOPY (gm./100 ml.)

Portion	Total solids	Lactose
Top	3·6	2·23
Bottom	30·8	7·31
Milk before freezing	8·1	4·63

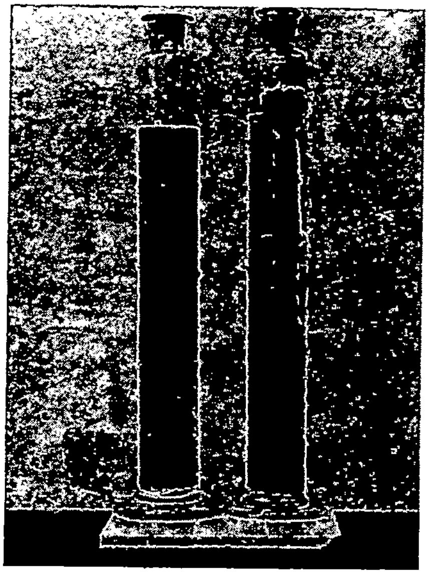

Fig. 1. Columns of potassium permanganate. Left, solution before freezing; right, after freezing. Note the cone of concentrated solute in the frozen column

These figures clearly bring out the high concentration of the solids at the bottom of the column on freezing. It is also noteworthy that the degree of concentration differs from constituent to constituent.

Use of whole milk interferes only with the visible separation of the solids, since the watery top-layers are masked by a plug of light fat.

Table 2. CONCENTRATION OF WHOLE MILK BY CRYOSCOPY (gm./100 ml.)

Portion	Total solids	Fat	Solids-not-fat
Top	8·439	3·24	5·199
Bottom	30·66	7·45	23·21
Milk before freezing	14·03	5·2	8·83

The 'cryoscopic effect', as the phenomenon may be called, is common to crystalloids as well. Solutions of copper sulphate, potassium permanganate and potassium ferrocyanide, similarly frozen and thawed, yield a higher concentration of the salts at the bottom of the column, at once evident by the greater intensity of colour. The disparity in concentrations of the salts between the top and bottom layers of the melted column can be seen in Table 3.

Table 3. CONCENTRATIONS OF CRYSTALLOIDS BY CRYOSCOPY (gm./100 ml.)

Portion	Copper sulphate	Potassium permanganate	Potassium ferrocyanide
Top	2·328	0·035	0·382
Bottom	7·950	0·230	6·410
Solution before freezing	2·739	0·052	1·008

The frozen column of potassium permanganate exhibits a vivid concentration gradient of the salt in the form of a purple cone with its base at the bottom. It is perhaps typical of cryoscopic concentration of solutes. Possibly this can be verified by using X-rays or by the tracer technique in relatively opaque frozen columns of other solutes.

In order to obtain a three-dimensional picture of the concentration of solutes in the frozen column, annular portions of the melts (simultaneously with analyses of top and bottom portions in another column) were analysed, as the thawing progressed.

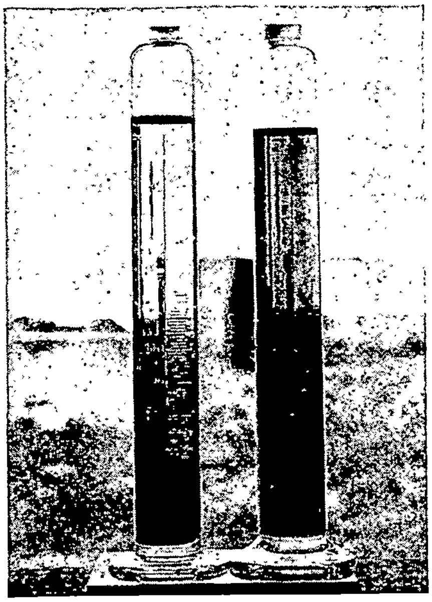

Fig. 2. Columns of potassium permanganate. Left, after freezing and thawing. Note heavy concentration of solute at the bottom. Right, original solution without freezing. Dark streaks in the centre of the columns are due to photographic effects

The average concentrations of salt in the concentric layers of the column from outside inwards, as well as the concentrations of the top and bottom in the second column of each salt, are given in Table 4.

Table 4. CONCENTRATION OF ANNULAR LAYERS AND VERTICAL PORTIONS OF FROZEN COLUMNS OF SOLUTIONS (gm./100 ml.)

Portion	Copper sulphate	Potassium permanganate	Potassium ferrocyanide	Skim milk
Outer layer	4·05	0·091	2·192	11·49
Thawing time (min.)	30	35	28	40
Middle layer	2·775	0·08	—	8·962
Thawing time	60	75	—	85
Inner layer	1·495	0·06	0·840	5·814
Thawing time	135	110	65	145
	Top and bottom portions in second column			
Top	2·328	0·035	0·382	2·378
Bottom	7·95	0·23	6·410	26·918
Solution before freezing	2·739	0·052	1·008	9·2834

These results give an insight into the pattern of concentration of solutes on freezing. The heaviest concentration seems to be a hollow ring at the bottom of the column. It is probable that a predictable relation exists between the solute concentration at the bottom of the frozen column and the concentration of the original solution, the molecular weight of the substance, the height and diameter of the frozen column.

The cryoscopic phenomenon may be of general use in analytical procedures and manufacturing processes, particularly where dilute solutions are involved and distillation is unsuitable. It may be possible to concentrate the heavy water fraction in water by repetitive cryoscopy for the atomic energy industry.

I thank Mr. A. E. Owen for his assistance in the analyses of the samples, and Drs. Anantakrishnan and Sethu Rao for experimental facilities at the National Dairy Research Institute, Bangalore.

CHEMISTRY

Differential Thermogravimetry versus Differential Thermometry in studying the Pyrolysis of Polymers

ORDINARY chemical methods of analysis are impractical for studying the pyrolysis of highly cross-linked polymers, because such materials are extremely infusible, insoluble and non-volatile. Techniques such as differential thermometry and differential thermogravimetry are therefore being used more and more for this purpose. Differential thermometry measures the net heats of reaction produced by chemical change as a function of temperature, whereas differential thermogravimetry measures loss of weight. Since the endothermic breaking of and the exothermic forming of bonds occur simultaneously in the pyrolysis of substances, differential thermometric information can be misleading. For example, if, at a given temperature, the heats of the endothermic reactions were exactly equal to the heats of the exothermic ones, a differential thermometric peak would be absent. This would lead to the false conclusion that no thermal decomposition had occurred. Changes in specific heat and in thermal conductivity of a polymer during pyrolysis also complicate the differential thermometric picture, especially when quantitative information is desired. Since differential thermogravimetry measures losses of weight during pyrolysis rather than heat changes, it is not subject to the above-mentioned complications, and should therefore give a more reliable quantitative estimate of the relative thermal stabilities of different polymers.

An example of this difference in reliability of the two methods may be had by comparing the corresponding data obtained for two epoxide polymers having different chemical structures. These polymers were prepared by treating dipentene dioxide in one case and vinyl*cyclo*hexene dioxide in the other case with one mole of methyl nadic anhydride per epoxy equivalent, using 1 per cent N,N-dimethylbenzylamine as a catalyst.

Both the differential thermometric and differential thermogravimetric experiments were performed at a heating rate of 5 deg. C./min., the former in nitrogen at atmospheric pressure and the latter *in vacuo*. Descriptions of the apparatus and procedures have been given previously[1,2]. The differential thermogravimetric curves in Fig. 1 clearly show that the vinyl*cyclo*hexene dioxide polymer is more thermally stable than the dipentene dioxide one. The former polymer shows a maximum rate of loss of weight at 375° C., whereas the latter one shows a maximum rate at 265° C. This large difference in thermal stability of the two polymers is not revealed by the differential thermometric curves in Fig. 2. Actually, the differential thermometric peaks at approximately 275° C. for each of the two polymers indicate that the vinyl*cyclo*hexene dioxide polymer has its maximum rate of decomposition at the same temperature as the dipentene dioxide polymer. Furthermore, if the two methods are compared for only one polymer, the differential thermometric data can still be unreliable. For example, the differential thermometric curve for vinyl*cyclo*hexene dioxide indicates that much more decomposition occurred at 275° C. than at 360° C. This indication is also contrary to the more reliable differential thermogravimetry data.

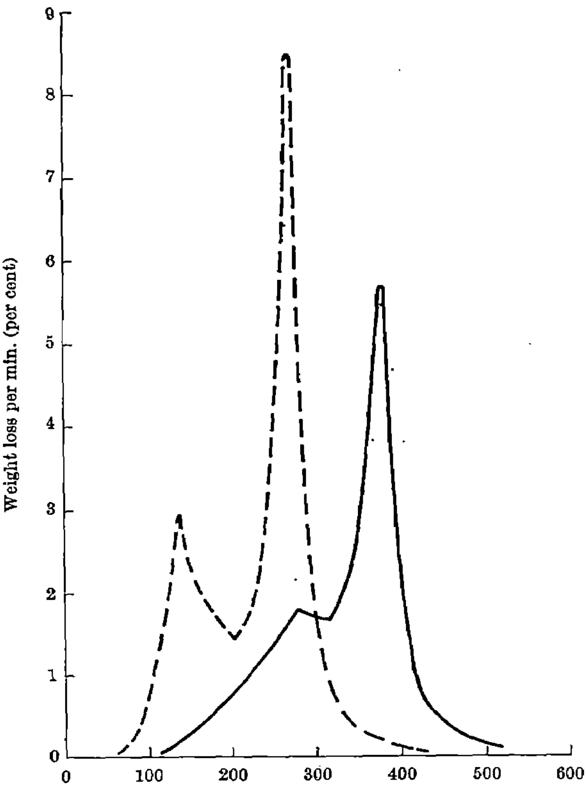

Fig. 1. Differential thermogravimetric curves. – – –, Dipentene dioxide polymer; ——, vinyl*cyclo*hexene dioxide polymer

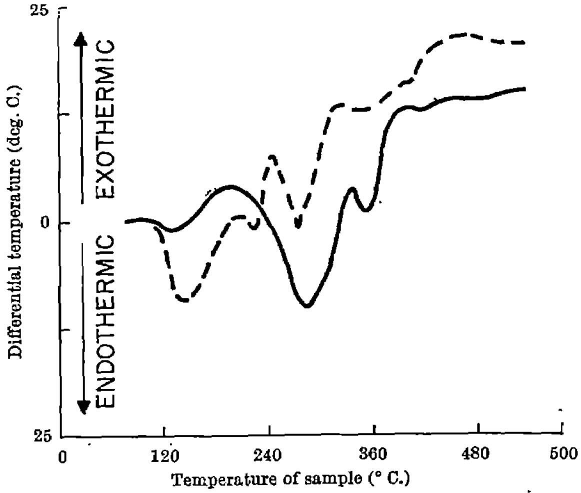

Fig. 2. Differential thermometric curves. – – –, Dipentene dioxide polymer (3·3 gm.); ——, vinyl*cyclo*hexene dioxide polymer (1·6 gm.)

Despite these shortcomings of differential thermometry as a tool for studying the pyrolysis of polymers, it can sometimes be very useful in revealing, or in clarifying, certain mechanisms of thermal degradation. For example, it has been shown by differential thermometry that isomerization of residual epoxy groups in certain epoxide polymers plays an important part in the decomposition mechanism[2]. It is therefore recommended that differential thermogravimetry be used to obtain quantitative information on the pyrolysis of polymers, especially highly cross-linked ones, and that differential thermometry be used as a qualitative adjunct.

Ionization Potentials of *cis* and *trans* Dichloro- and Dibromo-ethylenes

THE ionization potentials of pure *cis* and *trans* dichloro- and dibromo-ethylenes have been obtained by electron impact and by photon impact methods[1]. Table 1 gives my results and those obtained by Walsh[2] from Rydberg series.

Table 1. IONIZATION POTENTIALS (IN EV.) OF *cis* AND *trans* DICHLORO- AND DIBROMO-ETHYLENES

Substances	Walsh's results	Electron impact method	Photon impact method
cis $C_2H_2Cl_2$	9·66	9·67 ± 0·05	9·66 ± 0·02
trans $C_2H_2Cl_2$	9·96	10·00 ± 0·05	9·64 ± 0·02
cis $C_2H_2Br_2$		9·69 ± 0·05	9·45 ± 0·01
trans $C_2H_2Br_2$		9·54 ± 0·05	9·46 ± 0·01

I have observed in the photon impact efficiency curves the presence of singular points which I believe correspond to vibrationally excited states of the molecular ion. An example of this is given here for *trans* dichloroethylene (Fig. 1).

The singular points are as follows: *cis* dichloroethylene (9·77 ± 0·02 eV.); *trans* dichloroethylene (9·81 ± 0·02; 9·97 ± 0·03 eV); *cis* dibromoethylene (9·62 ± 0·02; 9·79 ± 0·02 eV.); for the *trans* dibromoethylene no sharp point appears.

From the values of the ionization potentials of ethylene, methyl chloride, and ethyl chloride, which are respectively 10·51, 11·28 and 10·97 eV. (ref. 3), it must be concluded that the electron

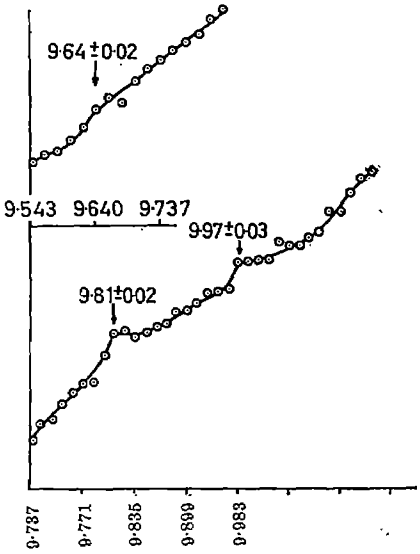

Fig. 1. Curve of photo-ionization efficiency (arbitrary scale) against photon energies (electron volts) for *trans* dichloroethylene

removed in the case of the dihalogenoethylenes is a πC=C electron. This and the order of magnitude of the jumps between two consecutive singular points indicate that the vibration involved is probably the C=C stretching vibration.

The electron impact and photon impact values are in rather good agreement for *cis* dichloro- and *trans* dibromo-ethylene, but an important discrepancy exists for *trans* dichloro- and *cis* dibromo-ethylene. From the vibrational separations of about 0·17 eV. observed for both substances, we conclude that the electron impact data correspond to the appearance of vibrationally excited states of the ion ($v=2$ for *trans* dichloroethylene and $v=1$ for *cis* dibromoethylene) and that the two other ions appear in the $v=0$ vibrational level for both photon and electron ionization.

Discrepancies of this nature between photon impact and electron impact ionization potentials are quite frequent and the interpretation given here seems to be of great generality. It conforms to the ideas of Mulliken[4], who considers photon impact potentials as "adiabatic" and electron impact potentials as "vertical" ones.

Further, from the equality of the formation enthalpies of the ions[1], it may be assumed that only one equilibrium configuration of the nuclei exists for the ion coming from a *cis* or from a *trans* isomer. This is in agreement with the theoretical work of Mulliken[5] on the $C_2H_4^+$ ion, the configuration of which he considers to be a crossed one.

By treating the dichloroethylene molecule and ion as diatomic vibrators with respect to the C=C bond, it may be shown that the results given here can be interpreted by assuming that the distance C=C is 0·035 Å. larger in the *cis* molecule and 0·065 Å. larger in its ion than in the corresponding *trans* dichloroethylene states.

I am indebted to the British Council and to the Patrimoine of the University of Liège for a grant, and to Prof. W. C. Price for permitting me to carry out the photo-ionization measurements in his laboratory at King's College, London. I wish to thank Prof. L. D'Or for the active interest he has shown in this work.

Rapid Determination of Ytterbium in Aqueous Solutions and in Thulium Oxide by Neutron Activation

IT is known that when natural ytterbium is irradiated with neutrons, ytterbium isotope of 6 sec. half-life is formed[1], and that this emits γ-rays of 0·104 MeV. and of 0·212 MeV.

In the present work, a sample (0·07 ~ 0·3 gm.) is placed in the nuclear reactor *JRR*-1 for 6 sec. to be irradiated with neutrons at a flux of 3×10^{11} neutrons per cm.^{2}/sec. and then the decay of the mixture of activities produced is determined by use of a 2-in. thick, well-type sodium iodide crystal attached to a 256-channel pulse-height analyser. In each of successive γ-spectra obtained, the height of the photopeak of the 0·104-MeV. γ-ray from 6 sec. ytterbium isotope is measured, and the decay curve is made by plotting the log peak height against time. Identification was by the γ-energy and the half-life. A calibration curve was prepared by activating and counting ytterbium solutions containing known amounts ranging from 0·01 to 1 mgm. of ytterbium.

Table 1. RESULTS OF ANALYSES OF THULIUM OXIDE

Sample	Sample weight used (mgm.)	Ytterbium found (per cent)	Dysprosium found (p.p.m.)
I	122	0·057	5·6
	76	0·062	6·2
II	124	0·083	5·5
	70	0·075	6·0

In the analyses of an aqueous sample, the coefficient of variation of single analyses was 5 per cent, where the content of ytterbium was 0·064 per cent and eight aliquots was used each of which was 0·25 ml. in volume. Since interfering activities were practically negligible and activities produced were on a level very suitable to the counter used, this value is felt to be the approximate lower limit of the coefficient of variation in this method.

In thulium oxide samples the resolution of the decay curve showed two components: a 6-sec. and a 1·3-min. The latter was identified to be dysprosium-165*m*. Dysprosium was then determined quantitatively by use of a calibration curve made by the method similar to that for the case of ytterbium mentioned above. Results of analyses of thulium oxide samples as fine powder are shown in Table 1.

Since ytterbium found and dysprosium found in Table 1 are nearly independent of sample weight used, it is deduced that self-shielding for neutrons in these samples was negligible. It has also been deduced from decay curves that, when a thulium oxide powder contains 6 p.p.m. dysprosium, the lower limit of the detection of ytterbium is about 0·01 per cent.

By a similar method using a 0·212-MeV. photopeak instead of a 0·104-MeV. photopeak reliable analyses of decay curves could not be attained.

I am indebted to Prof. Shoji Makishima for helpful suggestions, to Dr. Toshio Nakai for permission to use laboratory facilities, and to Dr. Yuichiro Kamemoto for help in the γ-ray spectrometry.

Stability Constant of Copper(II) Complexes of Reduction Products of 2,2'-Dipyridyl

THE ligand 2,2'-dipyridyl (DP), its derivatives and analogues form an extremely interesting and important class of ligands. Their complexes possess some particular properties, presumably as a consequence of π-electron system of the ligand. To elucidate the role of the π-electron system, the study of complex-forming properties of the reduction product of 2,2'-dipyridyl was undertaken. Although we are at the very beginning of a systematic investigation, nevertheless, we achieved some results worthy of publication.

2,2′-Dipiperidyl (DPP) was prepared from DP by hydrogenation at 100° C. under 120 atmospheres pressure, using Raney-nickel catalyst. The yield exceeds 90 per cent. The boiling-point of DPP at 6 mm. of mercury pressure is 100–105° C. 2,2′-Pyridylpiperidyl (PPP) was prepared also from DP by tin-hydrochloric acid reduction; after the reduction PPP was extracted from the alkalized solution by chloroform. The yield is about 70 per cent, the boiling point 265–266° C.

The acidic dissociation constants were determined by potentiometric titrations: 10^{-2} mole/l. solutions of ligands were titrated with 1 mole/l. hydrochloric acid at 20° C.; the solutions were of 0·1 mole/l. for potassium chloride. The values of acidic dissociation constants are shown in Table 1. For comparison acidic dissociation constants of DP (ref. 1) are also given.

Table 1

	K_1	K_2	K_1K_2	K_1/K_2
DP	1·59	$4 \cdot 27 \times 10^{-5}$	$6 \cdot 77 \times 10^{-5}$	$3 \cdot 72 \times 10^{4}$
PPP	10^{-2}	$7 \cdot 95 \times 10^{-10}$	$7 \cdot 94 \times 10^{-12}$	$1 \cdot 26 \times 10^{7}$
DPP	10^{-7}	$6 \cdot 90 \times 10^{-11}$	$6 \cdot 90 \times 10^{-18}$	$1 \cdot 45 \times 10^{3}$

As can be seen, the basicity of nitrogens increases with hydrogenation. It is interesting that the ratio K_1/K_2 is nearly the same in the case of DP and DPP, while it differs strongly from PPP due to the inequality of nitrogens in this compound.

The stability constants of copper(II) complexes of DPP and PPP were determined also by potentiometric titrations under the same conditions as the acidic dissociation constants of ligands. The values are tabulated in Table 2.

Table 2

	K_1	K_2	K_1K_2
PPP	—	—	$1 \cdot 59 \times 10^{12}$
DPP	$3 \cdot 16 \times 10^{10}$	$2 \cdot 75 \times 10^{7}$	$8 \cdot 69 \times 10^{17}$

It is worth mentioning that the ratio K_1/K_2 is exactly the same as in the case of N,N'-dimethylethylenediamine copper(II) complex studied by Irving and Griffiths[2].

In the case of PPP the formation function does not show a step at $\bar{n} = 1$. So the product, K_1K_2 could only be calculated.

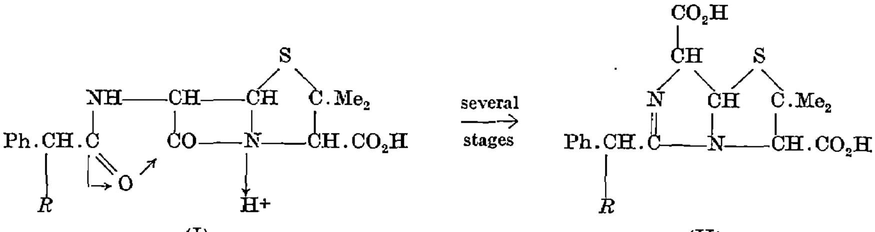
Some Novel Acid-stable Penicillins

Rapid inactivation of penicillins *F*, *G*, *K* and *X* in acid solution was demonstrated at an early date[1], and was widely assumed to be a general property until 1954, when phenoxymethylpenicillin (penicillin *V*) was shown to be relatively stable towards mineral acids[2]. The recent isolation in these Laboratories of 6-aminopenicillanic acid[3] permitted the synthesis of many hitherto inaccessible penicillins, including an extended series of acid-stable α-aryloxyalkylpenicillins[4] of which one, α-phenoxyethylpenicillin, is now in clinical use. Both penicillin *V* and its newer homologues are well absorbed from the gastro-intestinal tract and hence can be given by mouth, but they show useful antibacterial activity only against Gram-positive bacteria. Benzylpenicillin (penicillin *G*) has a broader antibacterial spectrum, but is not suitable for oral administration. We therefore prepared a series of α-substituted benzyl penicillins (I) in the hope of finding an acid-stable penicillin active against Gram-negative as well as Gram-positive bacteria.

The α-methoxy-, α-chloro-, and α-benzyloxycarbonylamino-compounds were prepared by treating 6-aminopenicillanic acid in aqueous sodium bicarbonate with an acetone solution of either the chloride or the mixed ethoxyformic anhydride of the appropriate α-substituted phenylacetic acid. The resulting penicillins were extracted from the acidified reaction mixture into ether, then re-extracted into aqueous sodium bicarbonate and freed from water by evaporation at low temperature and pressure. Hydrogenation of an aqueous solution of the sodium salt of α-benzyloxycarbonylaminobenzylpenicillin (I; *R* = $NH.CO_2.CH_2Ph$) over a palladium catalyst gave α-aminobenzylpenicillin[5].



(I) (II)

Specimens (50 mgm.) of each of the penicillins (I; *R* = H, OMe, Cl, and NH_2) were added to a mixture of 0·2 *N* aqueous hydrochloric acid (25 ml.) and ethanol (25 ml.) maintained at 35° C. and aliquot portions of each solution were withdrawn at intervals and the penicillin content determined by colorimetric assay with hydroxylamine[6]. The half-life of each penicillin was then read from the straight-line plot of log concentration against time. The results shown in Table 1 indicate that α-methoxy-, α-chloro-, and α-amino-benzylpenicillin are all much more stable to acid than is benzyl penicillin itself, while the chloro- and amino-compounds are also more stable than penicillin *V* (half-life 160 min.).

Table 1

	R = H	*R* = OMe	*R* = Cl	$R = NH_3^+$
Half-life of penicillin (I) in 50 per cent aq. EtOH at *p*H 1·3 and 35° C.	3·5 min.	77 min.	300 min.	660 min.
pKa of side-chain acid, $\mathrm{Ph.\underset{R}{CH}.COH}$, in 50 per cent aq. EtOH	5·6	4·6	4·0	3·2

Evidently benzylpenicillin can be rendered more stable to acids by the introduction into the α-position of the side-chain of electron-attracting substituents which might be expected to hinder the electron displacements initiating rearrangement to the isomeric biologically inactive penillic acid (II)[7]. Such stability would be expected to vary with the inductive effect of the substituent and hence to be roughly proportional to the strength of the side-chain acid from which the penicillin is derived. Support for this idea was obtained by potentiometric titration of the appropriate α-substituted phenylacetic acids against standard alkali in 50 per cent aqueous ethanol. Correlation of the *pKa* values calculated by the half-neutralization method with the acid half-lives of the corresponding penicillins is shown in Table 1.

As well as being the best of the new penicillins from the point of view of stability to acid, α-aminobenzylpenicillin also showed useful activity against a wide range of Gram-positive and Gram-negative bacteria both *in vitro*[8] and *in vivo*[9] and was well absorbed from the gastro-intestinal tract[9]. The epimer derived from D(–)α-aminophenylacetic acid was more active against most organisms than that from the L(+)-acid. Details of the preparation of it and some of its analogues will be published elsewhere.

We thank Dr. G. N. Rolinson *et al.* and Mr. D. M. Brown *et al.* for the bacteriological and chemotherapeutic testing of the penicillins and Mr. D. Neal for experimental assistance.

Crystallization of Isotactic Polypropylene using a Light Depolarization Technique

THE intensity of depolarized light transmitted by a thin film of isotactic polypropylene, crystallizing isothermally on a polarizing microscope hot stage was followed using a photomultiplier unit with an appropriate recorder system[1,2]. For the slower rates of crystallization, the cathode ray oscillograph–camera arrangement was replaced by a Honeywell Brown m.V. recorder. All measurements were made within the linear operating range of the equipment.

Dried sections (150–200μ) of unpigmented polymer chip of intrinsic viscosity 2·7 dl./gm., measured in tetralin at 135° C., were mounted between cover slips using *MS* 550 silicone oil as an immersion medium to reduce oxidation of the sample during melting. Specimens were melted at 270 ± 3° C. for 30 min. followed by rapid transfer (< 1 sec.) to the microscope hot stage maintained to within 0·5° C. of the desired crystallization temperature. Typical sigmoidal curves of the change in photomultiplier output with time were obtained and used as a measure of the extent of the crystallization. Results were fitted to Avrami equations after expressing them as a proportional change (I_c–I_t) relative to the overall primary change (I_c–I_0) associated with any isothermal[2]. I_c, I_t and I_0 are respectively equal to the final, intermediate and initial photomultiplier outputs. For the lower crystallization temperatures (< *c.* 80° C.) secondary or 'after' crystallization behaviour is frequently pronounced.

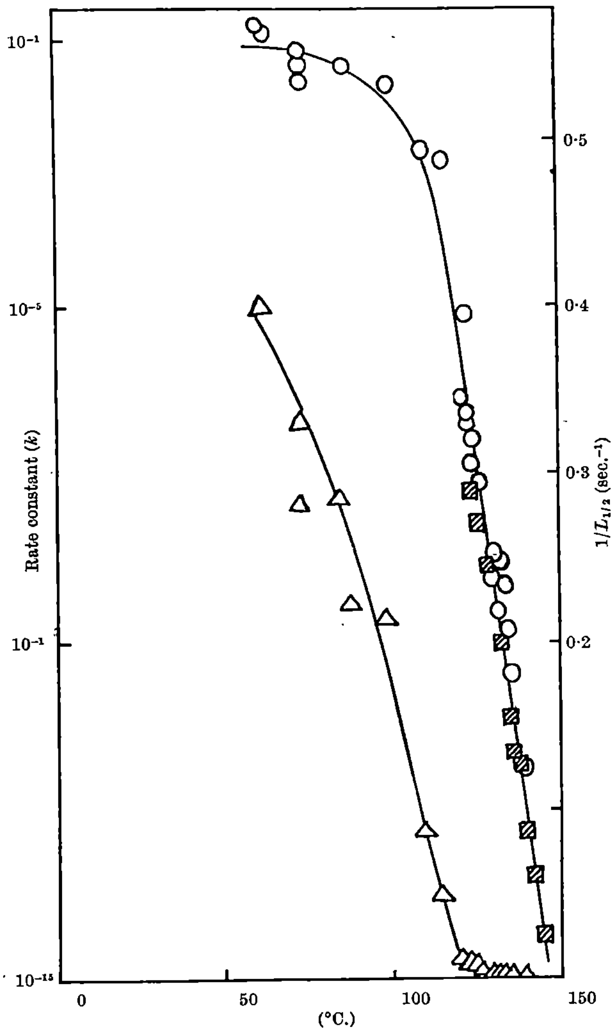

Fig. 1. Crystallization parameters for isotactic polypropylene polymer. Triangles, reciprocal of the half-times of crystallization temperatures (this work); circles, rate constants versus crystallization temperatures (this work); below and at 115° C. K is expressed in sec.$^{-2}$; above 115° C. K is expressed in sec.$^{-3}$

A change in the mechanism of nucleation occurs in the region of 115° C. Above this crystallization temperature spherulitic growth occurs from predetermined or simultaneous nuclei, while below 115° C. the structures formed are granular, and birefringent and nucleation is sporadic. The rate constants calculated from light depolarization isothermals (Fig. 1) agree well with published values derived from dilatometric measurements[3] for an isotactic polypropylene of similar intrinsic viscosity. The rate measurements presented here establish the utility of the technique for studying crystallization behaviour in polymers, and also its applicability over a wider temperature-range than most other established methods. Strain birefringence limits the use of the method at large degrees of supercooling where poor heat transfer is also significant[2].

BIOCHEMISTRY

Synthesis of Succinate from Acetate

In a previous communication[1], evidence was presented that an enzyme system, isolated from pig heart, catalysed the oxidation of acetate to succinate. Aconitase, assayed by the method of Racker[2], was not detectable and the addition of malate to the incubation mixture did not increase the incorporation of acetate into succinate. Consequently, the formation of succinate was attributed to a Thunberg condensation and the slow rate (7 mμmoles/hr./mgm. protein) was explained by the unfavourable equilibrium[3].

This explanation has been tested by attempting to measure the formation of acetate-^{14}C from succinate-2.3-^{14}C with preparations capable of incorporating acetate-^{14}C into succinate. Such experiments failed to demonstrate any significant formation of acetate, acetyl co-enzyme A or acetyl phosphate (when a preparation of transacetylase was added to the incubation mixture). These results indicate the absence of the Thunberg reaction and suggest that succinate is formed via the established reactions of the Krebs cycle—the slow rate being due to the extremely low activity of aconitase. Support for this view comes from the finding (Dr. T. M. Sutherland, private communication) that the incorporation of acetate into succinate disappears after dialysis of the enzyme system, but is restored by the addition of oxaloacetate.

It thus appears that the interpretation of the data in terms of a Thunberg condensation, for which I was solely responsible, was erroneous.

Conversion of Fibrin to Desmofibrin

In experiments on fibrin stabilization great difficulty has been encountered in obtaining a substrate free from fibrin-stabilizing factor (FSF)[1-5].

Such a substrate can be obtained from a fibrinogen preparation made by various methods, for example, from Kekwick's preparation[6] or, from oxalated plasma clotted with citrate thrombin[7]. From a clot mechanically released from a solvent or serum, a 2–4 per cent fibrin solution in urea solution at *p*H 5·2 (20 gm. urea in 100 ml. acetic buffer adjusted to *p*H 5·2 with acetic acid) is prepared.

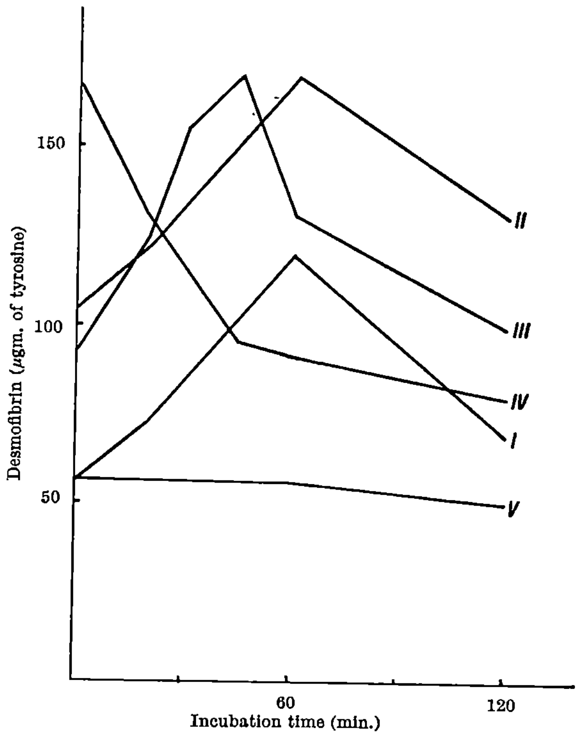

Fig. 1. Thrombinic activation of fibrin stabilizing factor in the presence of calcium. Incubated mixture: thrombin + FSF + calcium chloride. Curves I, II, V, 0·05 unit thrombin/ml.; curve III, 0·1 unit thrombin/ml.; curve IV, 1·0 unit thrombin/ml.; curves I, III, IV, V, 20 min.; curve II, 45 min. reaction of fibrin with incubated mixture; curve V, incubated mixture: thrombin + FSF without calcium chloride (calcium chloride was added just before mixing with fibrin monomer)

A fibrin solution from which the precipitates, regarded as being denatured, had been removed by centrifugation, was diluted 25–50 times in Palitzsch buffer solution[8] at *p*H 7·6, in which a fibrin network was immediately formed. This procedure of dissolving and repolymerizing of fibrin was repeated ten times.

Traces of thrombin could be identified in the diluent after the third repolymerization and removal of the clot. In subsequent operations, it was not possible to demonstrate the presence of thrombin, though it is known to be absorbed on the fibrin[9].

The product finally obtained is considered to be a fibrin monomer and it possesses the following properties: it clots immediately after dilution and neutralization, the time of polymerization depends on the concentration of salt and is lengthened if distilled water is used for dilution, the addition of thrombin has no effect on polymerization-time, provided that the concentrations of salt are constant.

The clot, that is, the fibrin polymer obtained from the monomer described here, is soluble in urea solution and in mono-chloracetic acid even when thrombin and calcium are added.

Stabilized fibrin polymer or desmofibrin is obtained by adding FSF, thrombin and calcium.

The fibrin polymer stabilization time and the amount of desmofibrin obtained in a definite period of time (for example, 20 min.) are proportional to the amounts of FSF added. With a constant FSF fibrin polymer, stabilization time and the amount of desmofibrin formed depend on the amount of thrombin added.

The experiment shown in Fig. 1 was carried out in two stages. In the first stage, three test-tubes containing a buffer solution at pH 7·6, FSF derived from platelets[10], and calcium in equal concentrations with citrate thrombin[7], the activity of which was, in the first test-tube 0·05 unit/ml., in the second, 0·1 unit/ml., and in the third 1 unit/ml. of the mixture, were incubated. At various intervals during incubation the incubated mixture was added to prepared test-tubes containing fibrin monomer.

In the second stage at various intervals after mixing the fibrin monomer with the incubated mixture the reaction was interrupted by adding mono-chloracetic acid and the amount of desmofibrin contained in the tubes was measured[11].

The experiment shows that during the reaction with FSF, when calcium and thrombin 0·05 unit/ml. and 0·1 unit/ml. are present, the fibrin-stabilizing activity increases and, during further incubation, it decreases (curves I, II, III).

Where 1 unit/ml. of thrombin is present, the high fibrin-stabilizing activity of the incubated thrombin, FSF and calcium is observed at the beginning of incubation (curve IV).

On comparing curves I and II, it will be seen that where 0·05 unit/ml. of thrombin is present, the peak of fibrin-stabilizing activity is observed 60 min. after incubation of thrombin, calcium and FSF. The conversion of fibrin polymer into desmofibrin takes place gradually, since after a 20-min. reaction of the incubated mixture with the fibrin polymer (curve I) it contains 120γ, after 45 min. (curve II) fibrin polymer contains 170γ of tyrosine expressed as the equivalent of desmofibrin.

During the incubation of thrombin and FSF without calcium, the fibrin-stabilizing activity does not increase (curve V). Stabilization of the fibrin polymer with this mixture and the addition of calcium correspond at the onset of incubation to that of the control in which all elements required in order to obtain desmofibrin are mixed simultaneously and, after further incubation, the stabilizing activity of the incubated mixture is lower than that of the control.
